Observations.—The oblique, imbricating lines on the outer surface of this species relate it closely to *Obolus* (*Westonia*) *bottnicus* (Wiman) and *O.* (*W.*) *wimani* Walcott. The two specimens showing the outer shell are unfortunately slightly worn along the median line, so that it is not possible to trace the growth of the oblique, imbricating lines entirely across the shell. In form the shell resembles *Lingulella acutangula* (Roemer).

FORMATION AND LOCALITY.—Middle Cambrian: (311x) Compact, fine-grained, quartzitic sandstone at Saltvik, Åland Island, Finland, Russia.

OBOLUS (WESTONIA) IPHIS Walcott

Plate XLIX, figures 4, 4a-d.

Obolus (*Westonia*) *iphis* Walcott, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 336. (Described as below as a new species.)

The general form of this shell is well shown by the illustrations. It differs from all other species of *Westonia* in having a more elongate and acuminate ventral valve and in the presence

of a marked mesial depression on the dorsal valve. The shell is rather thin and made up of several very thin layers or lamellæ. The outer surface is marked by fine radiating striæ, concentric striæ and lines of growth, and fine, more or less undulating, transverse lines that cross both the radiating and concentric lines. The transverse lines appear to be the edges of slightly elevated imbricating lamellæ of the shell.

FORMATION AND LOCALITY.—Lower Ordovician: (201a) *Pogonip limestone*, east slope of the ridge east of Hamburg Ridge, Eureka district [Hague, 1892, Atlas], Eureka County, Nevada.

Upper Cambrian: (64) Limestone near the Bullwhacker mine, Eureka district [Hague, 1892, Atlas]. Eureka County, Nevada.

(54j) About 700 feet (213.4 m.) above the Middle Cambrian and 525 feet (160 m.) below the top of the Upper Cambrian, in the arenaceous limestone forming 2c of the St. Charles formation [Walcott, 1908f, p. 192], in Blacksmith Fork Canyon, about 10 miles (16.1 km.) east of Hyrum, Cache County, Utah.

OBOLUS? (WESTONIA?) LAMELLOSUS (Barrande).

Plate XII, figures 7, 7a-d.

Lingula lamellosa BARRANDE, 1879, *Système silurien du centre de la Bohême*, vol. 5, Pl. CVI, figs. 1: 1-5; Pl. CXI, figs. IX: 1-3. (Not described, but figured as a new species. Pl. CVI, figs. 1: 2A, 1: 3f, and Pl. CXI, figs. IX: 2A; IX: 1A, and IX: 1f are copied in this monograph, Pl. XII, figs. 7, 7a-d, respectively.)

Obolus (Westonia?) lamellosus (Barrande), WALCOTT, 1901, *Proc. U. S. Nat. Mus.*, vol. 23, p. 691. (Merely changes generic reference.)

This species appears to be the Bohemian Lower Ordovician representative of *Obolus (Westonia) stoneanus* (Whitfield) of the Upper Mississippi Valley Middle Cambrian fauna. The two forms agree in relative size and proportions and in type of surface ornamentation. This may be seen by comparing figures 2, 2a-g, Plate XXVIII, with figures 7, 7a-d, Plate XII. Another point of similarity is that both species are very abundant in the localities in which they occur.

The principal differences to be noted are that *O.?* (*W.?*) *lamellosus* has apparently a thicker and stronger shell than *O. (W.) stoneanus*. This, however, may be due to the fact that all the specimens of the latter species are more or less flattened in the shaly sandstone, and that the shell substance has been largely removed by solution. It is on account of the resemblance of the two forms that Barrande's species is referred to the genus *Obolus* and subgenus *Westonia*, despite the absence of any knowledge of the area or the interior vascular markings or muscle scars.

It is hoped that the paleontologists of Bohemia will take up the study of this species and others that have been referred to *Obolus*, in order to establish clearly their generic relations.

FORMATION AND LOCALITY.—Lower Ordovician: (3031 [Barrande 1879b, Pl. CVI]) Étage d1, Libetschov, Bohemia, Austria-Hungary.

OBOLUS (WESTONIA) NOTCHENSIS Walcott.

Plate LXIII, figure 9.

Obolus (Westonia) notchensis WALCOTT, 1908, *Smithsonian Misc. Coll.*, vol. 53, No. 3, p. 69, Pl. VII, fig. 13. (Discussed as below as a new species. Fig. 13 is copied in this monograph, Plate LXIII, fig. 9.)

This species is represented by two specimens of the ventral valve that have the general outline of *Lingulella ampla* (Owen) (Pl. XXVIII, figs. 1a and 1f). The exterior surface is marked by concentric lines of growth and transverse, irregular, imbricating lines much like those of *Obolus (Westonia) stoneanus* (Whitfield) (Pl. XXVIII, fig. 2) and *O. (W.) iphis* (Pl. XLIX, figs. 4a-c). The form of the valve differs from that of the latter species.

The largest specimen has a length of 11 mm., with a maximum width of 9 mm.

The specific name is derived from Notch Peak, Utah, on which the species occurs.

FORMATION AND LOCALITY.—Lower Ordovician: (105t) Thin-bedded, bluish-gray limestone [Walcott, 1908f, p. 173 and Pls. XIII and XIV], at the summit of Notch Peak, House Range, Millard County, Utah.

OBOLUS (WESTONIA) ROGERSI (Walcott).

Plate XLII, figures 2, 2a-d.

Lingula prima ROGERS [not CONRAD MS., HALL], 1861, *Proc. Boston Soc. Nat. Hist.*, vol. 7, p. 390. (Mentioned.)
Lingula antiqua ROGERS [not EMMONS], 1861, *idem*, p. 390. (Mentioned.)

Obolus (Lingulella) rogersi WALCOTT, 1898, Proc. U. S. Nat. Mus., vol. 21, pp. 413-415. (Described and discussed essentially as below as a new species.)

Lingulella rogersi (Walcott), GRABAU, 1900, Occas. Papers Boston Soc. Nat. Hist., No. 4, vol. 1, pt. 3, pp. 624-625, Pl. XXXI, fig. 4. (Described and discussed.)

Obolus (Westonia) rogersi WALCOTT, 1901, Proc. U. S. Nat. Mus., vol. 23, p. 691. (Merely changes generic reference.)

General form elongate ovate, with the ventral valve subacuminate and the dorsal valve ovate in outline. There is considerable range of variation in the outline of the valves, owing largely to distortion apparently produced by movement of the matrix. The convexity of the valves is fairly strong and nearly the same in both, except that the dorsal valve curves more abruptly inward toward the beak.

The outer surface of the shell usually adheres to the matrix, but, in three specimens, portions of it are preserved which show that it is of essentially the same character as that of *Obolus (Westonia) stoneanus* (Pl. XXVIII). The surface is formed by very fine concentric lines and striae of growth crossed transversely by strong, undulating, slightly lamellose lines (Pl. XLII, figs. 2 and 2d). When the outer layer is exfoliated the inner layers are marked by concentric lines of growth and fine radiating striae. This is also the character of the inner surface, so far as can be determined from the specimens in the collection. The shell is rather thick and built up of a thin outer layer and several inner layers or lamellæ, the latter becoming increasingly numerous toward the front. The largest dorsal valve in the collection has a length of 13 mm. with a width of 11 mm., and a smaller ventral valve with a length of 12 mm. has a width of 9 mm. The dimensions of most of the specimens in the collection average less than those here given.

The area of the ventral valve is relatively short for a species of this type. It is divided midway, as seen in the cast, by a strong pedicle furrow. Owing to the imperfection of the material, none of the specimens show flexure lines or striae of growth. The area of the dorsal valve is short and extends but a short distance on either side of the median line. The cast of the interior of the ventral valve is very much like that of the interior of *Obolus cyane* (Pl. XVII). It has the same median ridge and the transverse trapezoidal area which includes the central, middle lateral, and outside lateral muscle scars. The main vascular sinuses are indicated by slight ridges (Pl. XLII, figs. 2a and 2b). The cast of the interior of the dorsal valve shows a narrow median septum, two central muscle scars of average size, situated a short distance back of the center of the shell, and two small anterior lateral scars, located some distance in advance of the center, which give an elongated visceral cavity somewhat like that of *Lingulella hayesi* (Pl. XXV) of the Middle Cambrian and *Obolus lamborni* (Pl. XXII) of the Upper Cambrian.

Observations.—The external form of the more elongate specimens of this species is very much like that of *Lingulella acutangula* (Roemer) (Pl. XVII). When compressed laterally it occasionally has the form of *Lingulella (Lingulepis) acuminata* (Conrad). It is distinguished, however, from all described species of *Westonia* known to me by its highly characteristic surface ornamentation. *Obolus (Westonia) stoneanus* (Pl. XXVIII) has the same type of surface, but it differs from the latter in being a much more elongate shell.

The material described in this monograph was collected by Prof. N. S. Shaler and Mr. J. B. Woodworth from the pebbles on the beach on the northern shore of Marthas Vineyard, Massachusetts, and at several points along the shores of Narragansett Bay.

The first notice we have of these fossiliferous pebbles is that by W. B. Rogers, who [1861, p. 389] announced the discovery, by Norman Easton, of pebbles carrying fossils of the Potsdam fauna in the Carboniferous conglomerate north of Fall River, Massachusetts. In 1875 [p. 100] Rogers announced the discovery of impressions, suggestive of the fossil *Lingulas* mentioned by him from Fall River, in the pebbles in the conglomerate at Newport, Rhode Island. He thought that the pebbles were derived from rocks probably closely connected in time with the Braintree *Paradorides* zone.

Among the material sent by Professor Shaler I found the remains of a large Linguloid brachiopod, which appears to be identical with *Obolus (Lingulobolus) affinis* (Billings), from the Lower Ordovician rocks of Newfoundland. The material is somewhat imperfect, but I

do not know of any other large brachiopod of this type from the Cambrian or Ordovician rocks. The reference to the Lower Ordovician is made by reason of the presence of this *Lingulobolus*.

The specific name is given for Mr. W. B. Rogers, who first called attention to the species.

FORMATION AND LOCALITY.—**Lower Ordovician:** (326) Limestone pebbles on the beach on the northern shore of Martha's Vineyard; and (326a [Grabau, 1900, p. 613]) limestone pebbles in a Carboniferous conglomerate north of Fall River, Bristol County; both in Massachusetts.

(343 [Rogers, 1875, p. 11, and *U. S. Nat. Mus.*]) Limestone pebbles on the beach near Newport and at several points along the shores of Narragansett Bay, Rhode Island.

(114b) Sandstone 1 mile (1.6 km.) north of Lance Cove, Great Belle Island, Conception Bay, Newfoundland.

OBOLUS (WESTONIA) STONEANUS (Whitfield).

Plate XXVIII, figures 2, 2a-g; Plate XLIX, figures 2, 2a.

Lingula aurora var. HALL, 1863, Sixteenth Ann. Rept. New York State Cab. Nat. Hist., pp. 127-128, Pl. VI, figs. 6-8. (Described and discussed.)

Lingulella aurora var. HALL, 1873, Twenty-third Ann. Rept. New York State Cab. Nat. Hist., pp. 244-245, Pl. XIII, fig. 5. (Mentions change of genus. Fig. 5 is drawn from the same specimen as Hall, 1863, Pl. VI, fig. 7.)

Lingulella stoneana WHITFIELD, 1882, Geology of Wisconsin, vol. 4, pp. 344-345, Pl. XXVII, figs. 6 and 7. (Characterized and discussed as a new species.)

Lingulella stoneana Whitfield, HALL and CLARKE, 1892, Nat. Hist. New York, Paleontology, vol. 8, pt. 1, Pl. II, figs. 9-11. (No text reference. Figs. 9 and 11 are copied from Hall, 1863, Pl. VI, figs. 7 and 8, respectively; and fig. 10 from Hall, 1873, Pl. XIII, fig. 5.)

Lingulella stoneana Whitfield, WELLER, 1903, Geol. Survey New Jersey, Rept. Paleontology, vol. 3, p. 112, Pl. I, fig. 6. (Described and discussed. The specimen represented by fig. 6 is redrawn in this monograph, Pl. XLIX, figs. 2 and 2a.)

Obolus (*Westonia*) *stoneanus* (Whitfield), WALCOTT, 1901, Proc. U. S. Nat. Mus., vol. 23, p. 691. (Merely changes generic reference.)

In form *Obolus* (*Westonia*) *stoneanus* (Pl. XXVIII) approaches quite closely to the more rounded shells of *Lingulella ampla* (Owen), except that in the dorsal valve the posterior lateral slopes are broadly rounded, giving a subelliptical outline to the valve. The original convexity of the valves is not preserved, but it appears to have been moderate, like that of *Lingulella ampla*. A large ventral valve from Prairie du Sac has a length of 15 mm., with a maximum width of 11 mm. An associated dorsal valve, 10 mm. wide, has a length of 11.5 mm. The surface of the shell is strongly characteristic. It is formed by very fine concentric lines or striae of growth crossed transversely by strong, undulating slightly lamellose lines (Pl. XXVIII, fig. 2d, and Pl. XLIX, fig. 2a). The margins of the inner surface of the shell show fine radiating lines. All of the large number of specimens in the collection are flattened in the shaly sandstone, and there is usually little left of the substance of the shell to afford a basis for an opinion of the form or thickness. A careful study of the material, however, leads to the conclusion that the valves were moderately convex and comparatively thin. In casts of the interior the concentric striae and transverse lamellose lines are almost invariably strongly marked, and no traces of the interior muscle scars or markings are preserved.

The area of the ventral valve, as seen in a cast, is divided midway by the cast of the strongly marked pedicle groove and, on each side and well out toward the margin, by the flexure lines. The few striae of growth preserved cross the area parallel to its base. On the dorsal valve the area is short, broad, and slightly arched forward near the center; the flexure lines are fairly well preserved in a compressed cast of the shell. No muscle scars or vascular markings have been observed on the interior casts of the ventral valve. A dorsal valve shows the central muscle scars (h) and the base of the main vascular sinuses (vs) (Pl. XXVIII, fig. 1h).

Observations.—This species was separated as a variety of *Obolus* (*Westonia*) *aurora* by Professor Hall [1863, p. 127]. Later [1882, p. 344], Professor Whitfield, finding that its peculiarities persisted in specimens found at localities where *O. (W.) aurora* did not occur, gave it a specific name. The peculiar surface ornamentation clearly distinguishes it from other species

of the genus except *O. (W.) aurora*, from which it differs in having a more elongate form and in the fact that the surface markings, though of the same type, vary in being much coarser and in having longer undulations. (Compare Pl. XXVIII, fig. 2d, with Pl. XLVI, fig. 1h.)

The form found by Stuart Weller [1900, p. 112] in the Upper Cambrian sandstones of northern New Jersey is illustrated on Plate XLIX, figures 2, 2a.

The specific name was given for Mr. R. E. Stone [Whitfield, 1882, p. 345].

FORMATION AND LOCALITY.—Upper Cambrian: (85x) Upper beds of the "St. Croix sandstone" at Mazomanie, Dane County; (81b) "St. Croix sandstone" near Devils Lake, Sauk County; (328m) sandstone 1 mile (1.6 km.) south of Osceola, Polk County; (328f [Hall, 1863, p. 128]) sandstone at the falls of St. Croix River, Polk County; and (85 and 85s)^a "St. Croix sandstone" at *Prairie du Sac*, Sauk County; all in Wisconsin.

(11c) Hardyston quartzite [Weller, 1903, pp. 110 and 112], O'Donnell and McManniman's quarry, Newton, Sussex County, New Jersey.

(327) Arenaceous limestone east of Gold Camp; (327a) arenaceous limestone about 500 feet (152 m.) above the base of the Cambrian in McKinley Canyon; (327b) arenaceous limestone near the base of the section on the south side of Cerro Cuchillo; and (327c) arenaceous limestone in the Caballos Mountains (exact locality unknown); all in the Caballos Mountains, Sierra County, New Mexico.

OBOLUS (WESTONIA) THEMIS Walcott.

Plate XI, figures 2, 2a-c.

Obolus (Westonia) themis WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 336-337. (Described and discussed as below as a new species.)

General form subsemicircular, with the ventral valve subacuminate and the dorsal valve broadly ovate in outline. Valves rather strongly convex. Surface of the shell marked by strong concentric lines of growth with finer intermediate striæ; in addition there are very fine, irregular, raised, more or less transverse striæ that inosculate, forming a minutely papillose or granular surface much like that of *Obolus (Westonia) ella* (Pl. XLVII). It often occurs that the outer surface has been removed by attrition in the sand, so that the shell has a smooth polished surface. Owing to the condition of preservation the markings of the inner layers are not preserved. The shell is strong and thick in advance of the center. It is made up of the thin outer surface layer and several inner layers or lamellæ that in the posterior portions are slightly oblique to the outer surface. After the shell has attained a size of 2 or 3 mm. the lamellæ are more oblique to the outer surface and form a thick, strong shell, the outer edges of which often produce a rather rough surface. This is shown by the figures illustrating the species.

The largest ventral valve in the collection has a length and breadth of 10 mm.; a dorsal valve 10 mm. in length has a width of 11 mm. The only interior portions of the shell known are on a fragmentary ventral valve in which the visceral area does not reach the center, and the main vascular sinuses are about halfway between the center and the lateral margins of the valve.

Observations.—The general form of the shell is much like that of *Obolus loperi* (Pl. IX). It differs from the latter in surface characters.

FORMATION AND LOCALITY.—Middle Cambrian: (17c) Sandy limestone 235 feet (71.6 m.) above the "Tonto" sandstone, Grand View trail, north of Last Chance copper mine, south side of the Grand Canyon of the Colorado, Arizona.

OBOLUS (WESTONIA) WASATCHENSIS Walcott.

Text figures 41A-F, page 467; Plate XLIX, figures 5, 5a.

Obolus (Westonia) wasatchensis WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 3, pp. 69-70, Pl. VIII, figs. 1 and 1a. (Discussed as below as a new species. Figs. 1 and 1a are copied in this monograph as figs. 41A and 41D.)

This species is founded on some large shells that differ from *Obolus (Westonia) ella* (Hall and Whitfield) (Pl. XLVII) in attaining a larger size and greater proportional width and in

^a 85s is the type locality, though the specimens in the United States National Museum to which that number is assigned were collected much later than the type specimens.

having the surface marked by radiating lines that extend from the umbo with a gentle curvature toward the sides and front of the shell, so as to terminate at right angles to the margin, very much as in *Obolus (Westonia) finlandensis* (Pl. XLVIII, figs. 3 and 3a).

In the Blacksmith Fork section of the Middle Cambrian terrane in the Wasatch Mountains of northern Utah *O. (W.) wasatchensis* occurs 1,590 feet higher in the section than *O. (W.) ella*.

The specific name is derived from its occurrence in Wasatch Canyon, Utah.

FORMATION AND LOCALITY.—Middle Cambrian: (34u) Shales about 950 feet (289.6 m.) above the Cambrian quartzitic beds, 2 miles (3.2 km.) southeast of Muskrat Spring, on the northwest face of Grantsville Peak, Stansbury Range, Tooele County; and (33t) shale about 1,500 feet (457.2 m.) above the Brigham quartzite, 1 mile (1.6 km.) northwest of Geneva (Copenhagen), east of Brigham, Boxelder County; both in Utah.

(54q) Drift block supposed to have come from the horizon of Locality 32x; (32x) about 1,700 feet (518.2 m.) above the Brigham quartzite [Walcott, 1908a, p. 8], in shales correlated with the shales forming 2d of the Bloomington formation in Blacksmith Fork Canyon [Walcott, 1908f, p. 195]; and (33j) about 2,300 feet (701 m.) above the Brigham quartzite; all in Wasatch Canyon, east of Lakeview Ranch, 5 miles (8 km.) north of Brigham, Boxelder County, Utah.

(54h) About 3,140 feet (957.1 m.) above the Brigham quartzite [Walcott, 1908a, p. 8] and 1,050 feet (320 m.) below the Upper Cambrian in the limestones forming 1a of the Bloomington formation [Walcott, 1908f, p. 194]; and (54k) about 2,100 feet (640 m.) above the Lower Cambrian and 2,100 feet (640 m.) below the Upper Cambrian in the shales forming 2d of the Bloomington formation [Walcott, 1908f, p. 195]; both in Blacksmith Fork Canyon, about 10 miles (16.1 km.) east of Hyrum, Cache County, Utah.

(55d) About 2,000 feet (609.6 m.) above the Cambrian quartzitic beds, in a shale which is probably to be referred to the Bloomington formation [Walcott, 1908a, p. 7], on the south side of Twomile Canyon near its mouth, 2 miles (3.2 km.) southeast of Malade, Oneida County, Idaho.

FIGURE 41.—*Obolus (Westonia) wasatchensis* Walcott. A, Elongate ventral valve, the type specimen (U. S. Nat. Mus. Cat. No. 51733a). B, Interior view of an elongate ventral valve (U. S. Nat. Mus. Cat. No. 51737a). C, Interior of a broken, flattened ventral valve (U. S. Nat. Mus. Cat. No. 51734b). D, Exterior of dorsal valve (U. S. Nat. Mus. Cat. No. 51734a). E, Interior of a flattened dorsal valve (U. S. Nat. Mus. Cat. No. 51734c). F, Interior of a dorsal valve (U. S. Nat. Mus. Cat. No. 51734d).

The specimens represented by figures 41A and 41B are from Localities 54q and 55d, respectively; and those represented by figures 41C-F are from Locality 54k. Figures 41A and 41D are copied from Walcott [1908d, Pl. VIII, figs. 1 and 1a, respectively].

OBOLUS (WESTONIA) WIMANI Walcott.

Plate XLVIII, figures 5, 5a-b.

Lingula? sp. No. 1, WIMAN, 1902, Bull. Geol. Inst. Univ. Upsala, vol. 6, pt. 1, No. 11, p. 51, Pl. II, fig. 36. (Locality mentioned.)

Lingulella? sp. No. 1, WIMAN, 1902, idem, p. 52, Pl. II, fig. 30. (Locality mentioned. The specimen represented by fig. 30 is redrawn in this monograph, Pl. XLVIII, fig. 5.)

Lingulella? sp. No. 2, WIMAN, 1902, idem, p. 52, Pl. II, fig. 31. (Locality mentioned. The specimen represented by fig. 31 is redrawn in this monograph, Pl. XLVIII, fig. 5a.)

Lingulella? sp. No. 7, WIMAN, 1902, idem, p. 52, Pl. II, fig. 32. (Locality mentioned. The specimen represented by fig. 32 is redrawn in this monograph, Pl. XLVIII, fig. 5b.)

Obolus (Westonia) wimani WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 337. (Discussed essentially as below as a new species.)

The general form of this species is not unlike that of *Obolus (Westonia) bottnicus* (Wiman) (Pl. XLVIII). The cardinal slopes of the ventral valve are more rounded, which makes the valve broader near the center. All of the specimens are also smaller. The surface markings

are of the same character as those of *Obolus* (*Westonia*) *finlandensis* Walcott (Pl. XLVIII) and *O.* (*W.*) *bottnicus*.

It is not improbable that with the discovery of a large series of specimens the three species may be combined, or *O.* (*W.*) *bottnicus* and *O.* (*W.*) *wimani* placed as varieties of *O.* (*W.*) *finlandensis*.

For reference to the geological horizon of boulders on Eggegrund Island, similar to the ones containing this species, see description of *O.* (*W.*) *bottnicus*, page 454.

The specific name is given for Dr. Carl Wiman, of the University of Upsala.

FORMATION AND LOCALITY.—**Middle? Cambrian:** (311c, 311g, and 311i)^a *Drift boulders of bituminous sandstone, Nos. 7, 16, and 27* [Wiman, 1902, p. 57], on *Biludden, about 20 miles (32.2 km.) east of Gefle, Province of Gefleborg, Sweden.*

(311t) *Drift boulder of mottled calcareous sandstone* [Wiman, 1902, p. 57], at Öfverby, parish of Jomala, Åland Island, Finland, Russia.

OBOLUS (WESTONIA) sp. undt. a.

Fragments of a species of *Obolus* with a very minutely reticulated surface occur in association with *Cyrtoceras cambria* Walcott and suggest *Obolus* (*Westonia*) *ella*, except that the surface ornamentation is so minute that it can only be seen with a strong lens. The fragments indicate a shell about the size of *O.* (*W.*) *ella*.

FORMATION AND LOCALITY.—**Upper Cambrian:** (C56) Lower part of Chaumitien limestone, 25 feet below the top of Pagoda Hill [Blackwelder, 1907a, p. 42 (part of last list of fossils)], 1 mile (1.6 km.) west of Tsuan, Shantung, China.

OBOLUS (WESTONIA) sp. undt. b.

Fragments of a shell showing the characteristic surface ornamentation of *Westonia* occur in the Ordovician limestone, Eureka district, Nevada. The shell must have been at least as large as *Obolus* (*Westonia*) *stoneanus* (Whitfield), but the material is too imperfect for identification.

FORMATION AND LOCALITY.—**Passage beds** between the Upper Cambrian and the Ordovician: (205) siliceous limestone on Roundtop Mountain, Eureka district [Hague, 1892, Atlas], Eureka County, Nevada.

Genus LINGULELLA Salter.

[Lingula.]

Tellinomya McCoy [not Hall], 1854, *British Paleozoic Fossils*, p. 274. (Described from distorted specimens of *Lingulella davisii* (McCoy).)

Lingulella Salter, 1866, *Mem. Geol. Survey Great Britain*, vol. 3, p. 333. (Described and discussed as a new genus.)

"The name *Lingulella* was first introduced about 1861, with the late Dr. S. P. Woodward's full consent; and the name appears at page 9 of Sir Roderick Murchison's address to the geological section of the British Association, Manchester, 1861," but was not described (see Davidson, 1866, p. 55).

Lingulella Salter, Davidson, 1866, *British Fossil Brachiopoda*, vol. 3, pt. 7, No. 1, p. 55. (Original description copied and *Lingulella* discussed as either a genus or subgenus.)

Lingulella Salter, Davidson, 1868, *Geol. Mag.*, vol. 5, p. 304. (Genus discussed.)

Lingulella Salter, Dall, 1870, *Am. Jour. Conchology*, 2d ser., vol. 6, pt. 2, pp. 153 and 159. (Described.)

Lingulella Salter, MEEK, 1871, *Proc. Acad. Nat. Sci. Philadelphia* for 1871, vol. 23, pp. 186-187. (Notes on genus in discussion of "*Lingulella lamborni*.")

Type of genus.—*Lingula davisii* McCoy.

Valves subequal, equilateral; elongate ovate, broad ovate, or subtriangular in outline. Ventral valve usually subacuminate, with a distinct area, pedicle groove, and flexure lines. Dorsal valve somewhat shorter, less acuminate, and with a less clearly marked pedicle groove on the shorter area. Beaks terminate at the margin of the areas, which are usually in the plane of the margins of the valves; the areas, which vary in size and shape in the different species, are usually more or less triangular; in the ventral valve they may be so shortened and arched as to nearly lose this marked form; the areas of the dorsal valve also vary in their form length, and extension on the cardinal slopes.

Shell substance calcareoconeous; structure consists of a thin outer surface layer and numerous inner layers or lamellæ that are subparallel to the surface over the posterior portions of the shell and more or less oblique to it over the central, lateral, and anterior portions; the short oblique layers usually form the inner flattened rim of the valves which is frequently seen in the casts (Pl. XVII, fig. 1i). Surface of shell marked by fine concentric striæ and lines of growth, and in some species finely inosculating, lamellose striæ; also, in most if not all species, radiating striæ and lines.

The visceral area (splanchnocœle [Mickwitz, 1896]) is usually confined to the central and posterior portions of the ventral valve, but it may extend far into the brachial area (brachio-cœle [Mickwitz, 1896]) (Pl. XVII, fig. 1c); in the dorsal valve it extends farther forward than in the ventral valve of the same species; in both valves it may range from the posterior third of the shell forward to the anterior third, and in the dorsal well into the latter; in both valves the visceral area extends back to the base of the areas where it is bounded exteriorly by the flexure lines (lines of folding of the area lamellæ).

A narrow median ridge or septum is frequently observable in the dorsal valve, but with the exception of what may be considered as indicating its probable presence in one specimen of a ventral valve of *Lingulella davisii* (McCoy) (Pl. XXXI, fig. 6f), no traces of a septum have been observed in the ventral valve of any of the species that I have studied. The main vascular sinuses vary in size, direction, and length in the various species; in all they begin in front of the area at the median line and extend forward and outward across the parietal band into the central-lateral and anterior parts of the brachio-cœle. The impressions of the secondary vascular canals are rarely preserved, but the few traces observed indicate that they were numerous and extended toward the peripheral canal and into the middle of the shell in the direction necessitated by the arrangement of the main sinuses and the boundaries of the visceral area.

In the anterior portion of the visceral area of the dorsal valve of some species the "heart-shaped pit" of *Obolus* is distinctly marked (Pl. XVII, fig. 1f). It is rarely so well shown, although its anterior outline is preserved in nearly all species whose interior characters are well marked. A median ridge may or may not be present in the interior of the dorsal valve.

The preservation of all vascular markings depends largely on the thickness of the shell, being rarely seen in thin shells and often found in thick ones.

There are six pairs of muscle scars that have been observed, in addition to the pedicle scar (m) which is situated on the ventral valve between the two scars (gg) left by the divided umbonal muscle close to the area; on the dorsal valve the single umbonal scar (g) is just in advance of the base of the area. The central scars (h) are usually situated about the center of the dorsal valve a short distance each side of a median septum; in the ventral valve they are inclosed in a trapezoidal area (c), with the scars of the outside and middle lateral muscles, on each anterolateral side of the heart-shaped area (x). The transmedian scars are shown as one scar on each side a little in advance of and on a line with the flexure lines of the area; the variation in their relative position in the two valves and in various species may best be understood by studying the illustrations and descriptions of species. The scars (k) of the middle lateral muscles are inclosed within the area (x) with the central and outside laterals; in the dorsal valve they blend with those of the outside laterals (l) in advance and a little outside of the transmedian scars (i). As previously stated, the scars of the outside lateral muscles in the ventral valve are combined with the central and middle laterals, while in the dorsal valve they are united with the middle lateral muscles. The scars of the anterior lateral muscles (j) of the ventral valve are usually so closely united with those of the transmedians (i) that it is only in unusually well-preserved specimens that the two scars can be differentiated; in the dorsal valve they are more or less in advance of the centrals, and divided by a narrow median septum or ridge; they may be situated a little back of the center of the valve or at any distance between that and a short distance from the frontal margin of the shell. In both valves the scar of the parietal band closely circumscribes all muscle scars externally, crossing the main vascular sinuses and terminating at the base of the flexure line of the area.

The principal forms of *Lingulella* may be grouped under five divisions by the outlines of the ventral valve.

Acuminate:

- Lingulella perattenuata* (Pl. XXI).
- L. acutangula* (Pl. XVII).
- L. manticula* (Pl. XX).
- L. nanno* (Pl. XXIV).

Subacuminate:

- Lingulella davisi* (Pl. XXXI).

Ovate-elongate:

- Lingulella bella* (Pl. XIX).

Ovate-quadrangular:

- Lingulella mosia* (Pl. XVIII).
- L. winona* (Pl. XVIII).

Subtriangular:

- Lingulella auga* (Pl. XXIV).

Intermediate forms are illustrated by *Lingulella martinensis* (Pl. XXXVIII), which is rounded subtriangular and acuminate, and *L. phaon* (Pl. XXVI), which is both acuminate and subacuminate.

The outline, relative size, and position of the visceral areas (splanchnocœles) are exceedingly variable.

In *Lingulella oweni* (Pl. XVIII) the area is very short, while in *L. acutangula* (Pl. XVII), *L. perattenuata* and *L. similis* (Pl. XXI), *L. punctata* (Pl. XX), and *L. radula* (Pl. XLV) it is elongate. The narrow type of visceral area in the dorsal valve is seen in *Lingulella acutangula* (Pl. XVII), *L. hayesi* (Pl. XXV), *L. similis* (Pl. XXI), *L. manticula* (Pl. XX), *L. leos* (Pl. XXIV), *L. ampla* (Pl. XXVIII), and *L. radula* (Pl. XLV).

The surface characters vary from the almost smooth and highly polished *Lingulella nanno* (Pl. XXIV), on which only the faintest traces of radiating striæ and depressed rounded lines of growth are visible, to shells with strong concentric striæ and lines of growth, *Lingulella auga* (Pl. XXIV). Whenever the surface of the shell is sufficiently well preserved to permit close examination radiating striæ have been observed.

Observations.—Prior to the investigation of the material described and illustrated in this monograph,^a the data relating to *Lingulella* were too meager to permit detailed comparison with

^a Announced in a preliminary paper: Proc. U. S. Nat. Mus., vol. 21, 1898, p. 390.

other genera. The presence of a peculiar central channel in the cardinal area was the only character of importance observed by Davidson [1866, p. 55] that served to distinguish *Lingulella* from *Lingula*. In the original description, Salter [1866b, p. 333] calls attention to the resemblance of the muscular scars of *Lingulella* to those of *Obolus*, but he considers that the difference in relative position is sufficient to distinguish the two genera. Attention is also called [Salter, 1866b, p. 333] to *Obolella* Billings, and to the fact that the later figures of Billings "show a very different set of muscular scars." Davidson had the same material that Salter had and more, but was unable to find any satisfactory interiors, and hence left the genus as doubtful, evidently considering it as closely related to *Lingula*.

Mickwitz met with the same difficulty as Davidson, in having unsatisfactory material upon which to base an opinion. After stating [1896, p. 126] that *Obolella* Billings would probably have to make room for the genus *Obolus* Eichwald, he says: "Whether *Lingulella* Salter will share the same fate I will not venture to predict with the same degree of certainty, since the diagnosis and figures are even more imperfect than in Billings's genus."

When in Wales, in 1888, I made a small collection of *Lingulella davisii* (McCoy) at the type locality at Portmadoc, and later Mr. G. J. Williams sent me a number of fine specimens for study. With this material, supplemented by a beautiful series of specimens of a number of American species, it has been possible to obtain a clear conception of *Lingulella* and its relations to *Obolus*, *Obolella*, *Schmidtia*, *Lingulobolus*, *Lingulepis*, and *Lingula*.

The memoir of Mickwitz [1896] gave the genus *Obolus* a position that it had not held prior to his very thorough investigation. With his descriptions and plates and a fine suite of specimens worked out from material very generously given me by Dr. Fr. Schmidt, I have been able to make a series of comparisons with *Lingulella* that at times has led me almost to doubt the advisability of characterizing *Lingulella* as generically distinct from *Obolus*. This distinction is now based on the more elongate form of most of the species of *Lingulella*, and the greater thickness of the shell of the typical forms of *Obolus*. There are differences in the position, size, and form of the muscular scars, visceral area, and vascular canals of *Obolus* and *Lingulella*, but they are not greater than those between different species referred to *Lingulella*. The same general arrangement of muscle scars prevails, but on comparing the interior of the dorsal valve of *Lingulella davisii* (McCoy) (Pl. XXXI, fig. 6e) with that of *Lingulella acutangula* (Roemer) (Pl. XVII, fig. 1h) or *Lingulella ampla* (Owen) (Pl. XXVIII, fig. 1h) we find as great variation as when the comparison is made with the dorsal valve of *Obolus* (Pl. VII, figs. 6-9). The same is true of the ventral valve, although the means of comparison are in this case not so good. One of the oldest species of *Lingulella*, *L. granvillensis* Walcott (Pl. XXII) of the upper *Olenellus* zone, has the outline of *Obolus* (*Schmidtia*) *celatus* Volborth, and the interior markings of the ventral valve are also of the same type. *Lingulella acutangula* (Roemer) (Pl. XVII, fig. 1f) has the heart-shaped pit so characteristic of *Obolus* (Pl. VII, figs. 1-4) and the arrangement of the muscular scars is essentially as in *Obolus*, but the outline of the valve is much more elongate. *Lingulella davisii* (McCoy) and *Lingulella ampla* (Owen) vary decidedly from *Obolus* in the interior markings, but not more than *Lingulella ampla* differs from *Lingulella acutangula*. The variations are so well shown by the figures on the plates that detailed comparisons will not be entered upon.

Matthew [1899b, p. 201] proposed to distinguish *Obolus* from *Lingulella* by its—

roundness of outline, short cardinal area and depressed beaks, advanced position of muscle scars in the valve, and strong arch of the vascular trunks in the ventral as well as the dorsal valve. There is, however, a more important distinction, which, in consequence of imperfect preservation of the valves, can seldom be observed; that is, the position of the secondary muscles of the central group in the ventral valve, as compared with the great muscle of that group. In *Obolus* they are lateral, but in *Lingulella* anterior to the great muscle. This shows a radical difference of structure between the two genera.

I am not able to recognize as constant the characters mentioned by Matthew, owing to the great variation in the large group of species referred to *Obolus* and *Lingulella*. The data for a clear distinction of the two, *Obolus* and *Lingulella*, are still too limited for more than an arbitrary reference of *Lingulella* to a generic place in relation to *Obolus*. This is particularly

the case with the position of the muscle scars of the ventral valve to which Matthew refers. The central muscles of the ventral valve of *Obolus* vary greatly in the position of the points of attachment; this is shown by Plate VII, figures 1-13, for *Obolus apollinis*. The scars of the central muscles of *Lingulella* are rarely preserved so that they can all be identified; in one species, *Lingulella acutangula* (Pl. XVII, figs. 1c and 1g), they appear to be arranged as in *Obolus apollinis*. The same is true for *Obolus* (*Westonia*) *escasoni* (Matthew) (Pl. XLIX, fig. 1aa).

The genus *Schmidtia* Volborth is made a subgenus of *Obolus* by Mickwitz [1896, p. 25]. A comparison of typical specimens of *Obolus* (*Schmidtia*) *cclatus* Volborth and *Lingulella davisii* (McCoy) leads to the view that *Schmidtia* is identical with *Lingulella* except that *Lingulella* is a radially striated shell and *Schmidtia* is not. I did not fully appreciate this distinction when writing a preliminary notice [1898, p. 392] of the study of *Lingulella* and hence referred to *Schmidtia* as a synonym of *Lingulella*.

Any extended comparison with *Obolella* is unnecessary, as it is a thick, round-ovate shell with a cardinal area and pedicle opening unlike *Lingulella* or any of the subgenera of *Obolus*. *Lingulobolus* has the same arrangement of muscle scars as *Lingulella*, but differs in the greater thickness of the shell in both valves. *Lingulepis* is scarcely more than a very acuminate form of *Lingulella* with the area and visceral cavity of the ventral valve modified in shape to meet the extreme elongation of the posterior portion of the valve.

That *Lingulella* is closely related to *Lingula* is seen at once by comparing the markings on the interior of the two shells.

Under observations on *Obolus* (p. 375) the differences between *Obolus* and *Lingula* have been stated. *Lingulella* differs from *Lingula* in the same manner as *Obolus* in having its visceral area continued back to the posterior margin of the interior of the valves, but it has the same general form as *Lingula*. Without the interior of the valves for comparison it would be very difficult to determine that many of the Cambrian species were not true species of *Lingula*.

Matthew [1903, p. 105] refers a group of small shells heretofore placed under *Lingulella* to the Ordovician genus *Leptobolus* of Hall. He says:

Such forms have usually been included in *Lingulella*, but in addition to their minute size they are separated from that genus by important characters.

These little shells have thin test, weak umbones; vascular trunks are situated near the lateral margins, and both the central and lateral muscles in both valves are advanced far toward the front of the valves.

As a result of the examination of the types of the Ordovician species of *Leptobolus* I find that they have quite strong, thick shells in proportion to their size, quite as much so as the young shells of species of *Lingulella* that acquire thickened shells as they attain their full growth. The vascular trunks are well out toward the margin, but this feature also occurs in large forms of *Lingulella*, as indicated in the table under *Obolus* (p. 377). The position of the central and lateral muscle scars is also too variable a character to afford a basis for generic reference. *Leptobolus* is marked by a peculiar visceral area in the ventral valve unknown in any Cambrian shell, and the bifurcation of the strongly marked ridges of the path of advance of the central and lateral muscle scars in the dorsal valve is a distinguishing character not found in the Cambrian shells referred to *Leptobolus*. The Cambrian forms referred to *Leptobolus* by Matthew [1903] are: *L. atavus*, *L. atavus insulæ*, *L. atavus tritavus*, *L. collicia*, *L. collicia collis*, *L. flumenis*, *L. gemmulus*, *L. cf. linguloides*, and *L. torrentis*.

If the above species are included in a distinct genus, several others should go with them, notably: *Lingulella ferruginea* Salter (Pl. XXIX), *L. lepis* (Salter) (Pl. XXXI), and *L. cania* (Walcott) (Pl. XXXV).

One of the oldest species known of the genus *Lingulella*, *Lingulella schucherti* (Walcott) (Pl. XXI, fig. 6), is in all respects, so far as can be determined from the material, a true *Lingulella*. The shell is phosphatic, relatively thin, elongate, resembling in this respect *Lingulella acutangula* (Roemer) (Pl. XVII). From this it appears that we have in the *Olenellus* fauna of the Lower Cambrian, associated with *Obolella*, a typical representation of the genus *Lingulella*. This association shows that the differentiation in the group of brachiopods represented by *Lingula* and *Obolella*, or the Lingulidæ, had advanced a long way before the period in Lower

Cambrian time represented by the fauna at Troy, New York. It is to be borne in mind that the fauna at Troy was collected both from stratified and conglomerate limestones. On this account it is not practicable to state that all the species from either are from the same geologic horizon, but *Lingulella schucherti* (Walcott) (Pl. XXI) and *Obolella crassa* (Hall) (Pl. LIV) occur in the same pieces of limestone. *Lingulella granvillensis* Walcott (Pl. XXII) occurs at numerous places in Washington County, New York, in strata near the top of the Lower Cambrian zone. *Lingulella nathorsti* Linnarsson (Pl. XXXI, figs. 1, 1a-b) occurs in the *Holmia kjerulfi* zone of Sweden. It has nearly the outline of *Lingulella acutangula* (Roemer) in some examples of the ventral valve. (Compare Pl. XXXI, fig. 1c, with Pl. XVII, fig. 1a; and Pl. XXXI, fig. 1a, with Pl. XVII, figs. 1h-k; also fig. 1 on each of the two plates.) *Lingulella delgadoi* Walcott (Pl. XXIX, figs. 6 and 6a) from the *Olenellus* zone of Portugal is, from our present knowledge of it, a true *Lingulella*.

Matthew [1903, p. 109] in speaking of the growth of *Lingulella* and allied forms, speaks of a law that the young shells are often round and the adults more elongate. This is in accord with the view that the protogulum of all forms of the Atremata is semicircular or semielliptical. In *Lingulella* (*Lingulepis*) *gregwa* (Matthew) (Pl. XLIV) and *L. (L.) exigua* (Matthew) (Pl. XLIII) the young shells are more elongate than the adult, owing to the broadening of the anterior portions of the valves as they increase in size.

Lingulella? paliformis [Hall and Clarke, 1892c, Pl. II, figs. 6-8] has the form of some of the more acuminate species of *Lingulella*, but from a study of the type specimens I am led to conclude that the material is too limited to decide the true generic relations of the species. The area of the dorsal valve is like that of *Lingulella*, but the only specimen showing the area of the ventral valve suggests that the pedicle furrow was confined to the dorsal valve. Nothing is known of the interior markings of either valve.

The vertical range of *Lingulella* is from the upper horizon of the *Olenellus* or Lower Cambrian fauna to the summit of the Cambrian and into the Ordovician fauna. One of the oldest known species is *Lingulella schucherti* (Walcott), found in the limestone conglomerate at Troy, New York, in association with *Obolella crassa* (Hall), *Bicia gemma* (Billings), *Elliptocephala asaphoides* Emmons, etc. *Lingulella granvillensis* Walcott, which is associated with *Olenellus* in the strata referred to the upper portion of the *Olenellus* zone, *L. nathorsti* Linnarsson of the *Holmia kjerulfi* zone of Sweden, and *L. delgadoi* Walcott are found in association with *Olenellus*. The greatest development of the species is in the Middle and Upper Cambrian, only a few forms continuing on into the Lower Ordovician.

The small *Lingulella desiderata* ranges from the base of the Middle Cambrian in the Cordilleran region to the Ordovician. There may be specific differences, but in the large amount of material now available for study there are none that appear to be of specific importance. *Lingulella isse* also has a great vertical range.

Lingula attenuata Sowerby [Davidson, 1866, p. 44, Pl. III, figs. 18-27] has the form of *Lingulella* and may possibly be a survival into the Middle Ordovician of a species of the genus. We do not have sufficient data to know whether the interior markings of the valves are more like those of *Lingula* or *Lingulella*.

Of the 77 species and 4 varieties from the Cambrian referred to *Lingulella* in this monograph, 5 species occur in the Lower Cambrian, 46 species and 1 variety in the Middle Cambrian, 35 species and 3 varieties in the Upper Cambrian, 6 species in the passage beds between the Cambrian and the Ordovician, and there are 13 species from the Ordovician. Of the Middle Cambrian species 13 pass up into the Upper Cambrian, of which two are found in the Ordovician. Two species pass from the Upper Cambrian to the Ordovician and two from the Upper Cambrian to the passage beds.

The range of all known species is given in the tables of genera and species (pp. 98-113).

Subgenera of Lingulella.—*Leptembolon* Mickwitz [1896, p. 199] is rather difficult to characterize. Mickwitz [1896, p. 199] says of it:

The subgenus *Leptembolon* is based on a species of *Obolus* which externally resembles *Lingula* very closely, and in fact was regarded as such by earlier authors [Schmidt, Fr., 1881, p. 17]. The specimens of the internal surfaces

of the valves, however, showed, together with some suggestions of the last-mentioned genus (*Lingula*), unmistakable marks of the genus *Obolus*, so that the species, which would not be assigned to any of the other groups, had to be ranked in a special subgenus of Eichwald's genus.

Type.—*Obolus* (*Leptembolon*) *lingulæformis* Mickwitz (Pl. XIV, figs. 5, 5a-b).

Lingulepis Hall [1863, p. 129] is a *Lingulella*-like shell with the ventral beak much attenuated. *Type*: *Lingula acuminata* Conrad.

For the species hitherto referred to *Lingulella* that are now referred to other genera or subgenera see pages 58-62.

LINGULELLA ACUTANGULA (Roemer).

Plate XVII, figures 1, 1a-o.

Lingula acutangula ROEMER, 1849, Texas, p. 420. (Described in Latin and discussed in German as a new species.)

Lingula acutangula ROEMER, 1852, Kreidebildungen von Texas, p. 90, Pl. XI, figs. 10a-b. (Described in Latin and discussed in German.)

Lingulepis acutangulus (Roemer), SCHUCHERT, 1897, Bull. U. S. Geol. Survey No. 87, p. 259. (Merely changes generic reference.)

Obolus (*Lingulella*) *acutangulus* (Roemer), WALCOTT, 1898, Proc. U. S. Nat. Mus., vol. 21, pp. 392 and 394; Pl. XXVII, fig. 6; Pl. XXVIII, figs. 1 and 2. (Mentioned in the text in discussion of *Lingulella*. Figs. 6, 1, and 2 are reproduced in this monograph, Pl. XVII, figs. 1c, 1f, and 1h, respectively.)

General form elongate ovate with the ventral valve subacuminate and the dorsal valve ovate in outline. When the ventral valve is slightly compressed the cardinal slopes are often crushed down over the area about the pedicle groove, so as to make the outline of the valve more acuminate. This appears to be the case with the type figure of Roemer, and it is partly shown by Plate XVII, figure 1e. There is considerable range of variation in the outline of the valves (Pl. XVII). The convexity of the two valves is fairly strong, and it is nearly the same in each, except that the dorsal valve curves inward more rapidly toward the beak. A ventral valve 9 mm. in length has a convexity of 1.25 mm., and a dorsal valve 10 mm. long arches 1.5 mm. above the plane of the margin.

Surface of the shell marked by radiating and concentric striæ and lines of growth. The radiating striæ are usually indistinct, but in a number of shells they are well marked or interrupted somewhat by irregular rounded lines that alternate, blend, and disappear without any apparent system (Pl. XVII, fig. 11). The concentric striæ are fine, usually having an unbroken curvature, but in some instances they are broken into short undulations, such as characterize the surface of several other species of *Lingulella*. In some examples the undulations are close and pronounced, and form a fine broken reticulation that is discernible only with a strong magnifying glass. When the outer layer of the shell is partly exfoliated the radiating striæ appear as sharp, clear-cut lines, but they do not extend to the inner surface of the shell (Pl. XVII, fig. 11). The interior surface is usually marked by strong punctæ which vary greatly in number and arrangement. This is illustrated by the casts of the interior of several shells, where the punctæ are represented by papillæ. On figure 1c the papillæ are large and somewhat scattered, while in figure 1a they are smaller and arranged in concentric lines quite to the edge of the shell. In the dorsal valve the punctæ are not quite so strong and they do not extend out to the margin (Pl. XVII, figs. 1i, 1j, and 1k); in specimens showing the interior scars and markings the punctæ are less numerous (figs. 1f, 1h, and 1j).

The shell is thicker than in most species of the genus, in this respect resembling in a modified degree the type of *Obolus*, *O. apollinis* Eichwald. The shell is formed of a thin outer layer and several thinner layers or lamellæ that are slightly oblique to the outer layer (fig. 1m), a structure quite similar to that of the shell of the recent *Lingula anatina* Bruguière.

The longest ventral valve in the collection has a length of 14 mm., and a maximum width of 10 mm. Roemer's figure [1852, Pl. XI, fig. 10] is larger, 18 mm. by 13 mm. The average length of the ventral valve is from about 8 to 10 mm., and of the dorsal valve 6.5 to 8.5 mm. The relative dimensions of the two valves may be seen by a comparison of figures 1 and 1i, Plate XVII.

As determined by a study of interior casts, the plane of the cardinal area of the ventral valve coincides near its edges with the edge of the shell, rising slightly toward the deep, rounded pedicle furrow. The area is divided at the center by the pedicle furrow, and toward its margins by elevated lines, or extremely narrow ridges, that extend from the apex with a slightly outward curvature to the base of the area (the flexure marks of the area parallel with its base); they are rounded and strong in the pedicle groove, sharp and crowded on the lateral slopes; they cross the pedicle groove transversely, slope forward across the central spaces (splanchnocœle of Mickwitz [1896, p. 116]) curve almost backward in the flexure lines and slope forward at a low angle across the lateral spaces (pleurocœle of Mickwitz [1896, p. 116]). The area forms a thin shelf between the pedicle groove and the lateral margins, the undercut extending far back under the area. This is shown in the cast by a thin projection of the embedding rock over the area (Pl. XVII, figs 1a, 1c, and 1f), where the broken edges remain. The area of the dorsal valve is lower and less prominent; the striæ of growth cross it parallel to the anterior margin, being interrupted by the flexure lines, which are but slightly indicated on most specimens. The shallow furrow, corresponding to the pedicle furrow of the ventral valve, usually extends across the space between the flexure lines. The pedicle groove on the ventral valve is deep, narrow, and strongly defined, tapering very gradually from the anterior end toward the beak.

The cast of the visceral cavity (v), including the heart-shaped pit (x) of the ventral valve, is shown by Plate XVII, figures 1a, 1c, 1f, and 1g, the latter particularly well by figure 1f, where it strongly resembles the same space in *Obolus apollinis* Eichwald. There are no traces of a median septum in the ventral valve; in the dorsal valve it is shown in the casts as a very narrow, clearly defined, sharp depression (s) extending a short distance back of the central muscle scars, in some specimens, and forward nearly to the anterior lateral scars (Pl. XVII, figs. 1h and 1j).

The muscle scars are finely shown in casts of both valves. The umbonal scar (gg) of the ventral valve is divided as in *Obolus*, the pedicle scar (m) being situated between the two parts (Pl. XVII, fig. 1f); the latter are oval in outline, their longer axis being slightly inclined forward and outward. In the dorsal valve the umbonal scar (g) is very close to the area and extends across nearly the entire distance between the central portion of the area delimited by the flexure lines (Pl. XVII, figs. 1h and 1j). In one specimen fine striæ cross the scar subparallel to the median line of the shell.

The scars of the central muscles are not clearly defined in the ventral valve, owing to their being crowded in with the scars of the middle and outside laterals. Their position, judging from the location of the centrals in *Obolus*, is within the trapezoidal area (c) indicated on Plate XVII, figures 1f and 1g. The central muscle scars (hh) are large and distinctly defined on a number of casts of the interior of the dorsal valve. They are situated a little in advance of the center of the shell, on each side of the median septum, with their longer axis inclined outward at an angle of nearly 45° (Pl. XVII, figs. 1h and 1j). The anterior laterals (j) are clearly defined in both valves; their form, size, and position are shown by figures 1f and 1g for the ventral valve, and figures 1h and 1j for the dorsal valve. The middle and outside lateral scars on the ventral valve are situated in the trapezoidal area (c), but neither are clearly separable in any of the specimens in the collection unless it be in that represented by figure 1c, where a small round scar (k) occurs, corresponding in position to that of the middle lateral scars of *Obolus*. On the dorsal valve the middle and outside laterals are closely united as in *Obolus*, and they are apparently combined in the elongate scar (l) (Pl. XVII, figs. 1h and 1j). This scar corresponds in position with the two scars in *Obolus*, in which genus it is usually impossible to discover the line of demarcation between them. The transmedian scars (i) are distinctly shown on the dorsal valve (Pl. XVII, figs. 1h and 1j), but in the ventral valve they are so closely united with the anterior laterals (j) that it is impossible to differentiate them.

Portions of the markings left on the shell by the vascular system are finely preserved in a few casts of the interior of the valves. The description is of the present appearance of the casts, which is the reverse of the actual condition in the interior of the shell. The main or trunk

sinuses (vs) are indicated for the ventral valve in figure 1g, and for the dorsal valve by figures 1h and 1j. The latter are rather indistinct, rounded ridges, with a few lateral branches showing in the specimens. In figure 1g the interior lateral branches (ivs) are shown, and the peripheral sinuses (pvs) are seen in figures 1h and 1j, Plate XVII.

The parietal scar (ps) is distinctly shown in front of the visceral area of the ventral valve (Pl. XVII, fig. 1f), but it has not been traced outside of the main sinus. In one specimen of the dorsal valve its course may be followed from the median line in front of the anterior lateral muscle scars, curving outward to the main vascular sinus and outside of the sinus around the outside lateral, where it turns back toward the flexure line of the area (fig. 1j).

Observations.—The specimens described by Roemer [1849, p. 420] came from a limestone in San Saba County, Texas. He figures [1852, Pl. XI, fig. 10] a ventral valve that is larger and more acuminate than the majority of the specimens in the collection before me; but, in the absence of a closely allied species from the Cambrian of Texas, and in view of the fact that there is a considerable range of variation in the form of the valves, I do not hesitate to identify the form here described as belonging to the species studied by Roemer. He compares it [1852, p. 90] with "*Lingula cuneata*" of the Medina sandstone of New York, to point out that it is more acuminate than that species. It also differs from it in the character of the interior markings and muscle scars and the greater thickness of the shell. From other species of the genus, *Lingulella acutangula* varies in form and in the arrangement of the muscle scars. It is somewhat closely related to *Lingulella cuneola* (Whitfield) of the Middle Cambrian of the Black Hills, South Dakota, and the latter species may even be identical with it.

FORMATION AND LOCALITY.—**Upper Cambrian:** (14b) Limestone on Cold Creek at north end of gorge opposite the north end of Sponge Mountain, 2 miles (3.2 km.) south of the San Saba County line, in Llano County; (14i) upper part of the limestone exposed 1 mile (1.6 km.) west of Cherokee, San Saba County; (353) limestones [see Roemer, 1849, p. 420] on San Saba River, San Saba County; (68 and 68e) interbedded limestone and sandstone, Packsaddle Mountain, Llano County; (69) limestone, near Honey Creek, Burnet County; (67 and 67c) sandstone on Tatur Hill, 7 miles (11.2 km.) northwest of Burnet, Burnet County; (353c) heavy dark ferruginous sandstone collected somewhere in Llano County; and (70 and 70e) limestone, near Morgans Creek, Burnet County; all in Texas.

Middle Cambrian: (11j) Basal part of Bonnetterre limestone, Mine Lamotte, Madison County; and (11k) limestones of the "Edgewise beds," beneath the Elvins formation, St. Francois County; both in Missouri.

(17c) Sandy limestone, 235 feet (71.6 m.) above the "Tonto" sandstone, Grand View trail, north of Last Chance copper mine, south side of the Grand Canyon of the Colorado, Arizona.

Specimens that are somewhat doubtfully referred to *Lingulella acutangula* occur at the following localities:

Upper Cambrian: (327) Arenaceous limestone east of Gold Camp, in the Caballos Mountains, Sierra County, New Mexico.

(111) Arenaceous limestone of the Elvins formation, 50 feet (15.2 m.) above the "Edgewise beds," St. Francois County, Missouri.

Middle? Cambrian: (313c) Limestone 12 miles (19.3 km.) west-southwest of Alpha Station, Eureka County, Nevada.

LINGULELLA AGNOSTORUM (Wallerius).

Plate XXX, figure 15.

Lingula agnostorum WALLERIUS, 1895, Undersökningar öfver Zonen med *Agnostus lævigatus* i Vestergötland, pp. 64-65, figs. Sa-b. (Described in Latin, and discussed in Swedish, as a new species.)

Shell very small. Outline ovate, with the ventral valve subacuminate; moderately convex. Surface of shell marked by concentric striæ and strong growth lines that, near the umbo, form deep undulations separating the minute, elevated, smaller umbo from the less elevated concentric ridges in front of it. The ventral valve illustrated by Wallerius is about 3 mm. in length and that of the specimen before me is 1.5 mm. I have not seen a dorsal valve.

Observations.—This minute shell is associated with *Acrotreta parvula* (Wallerius) and *Agnostus lævigatus*. It differs from *Lingulella* sp. undt. a of the *Olenus truncatus* zone in its minute size, more acute beak, and less distinctly striate surface characters.

This form owes its specific name to its association with *Agnostus*.

FORMATION AND LOCALITY.—(310i) Limestone in passage beds between the Middle Cambrian *Paradoxides forchhammeri* zone and the Upper Cambrian *Olenus truncatus* zone; at Borgholm, on Oeland Island, Sweden.

LINGULELLA AMPLA (Owen).

Plate XXVIII, figures 1, 1a-j.

Lingula ampla OWEN, 1852, Rept. Geol. Survey Wisconsin, Iowa, and Minnesota, p. 583, Pl. I B, figs. 5 and 12. (Described as a new species, see p. 478 for copy. The specimen represented by fig. 5 is redrawn in this monograph, Pl. XXVIII, fig. 1.)

Lingula ampla Owen, HALL, 1863, Sixteenth Rept. New York State Cab. Nat. Hist., p. 125, Pl. VI, fig. 10. (Original description, Owen, 1852, p. 583, copied and species discussed.)

Lingula ampla Owen, HALL, 1867, Trans. Albany Inst., vol. 5, pp. 101-102, Pl. I, fig. 10. (Discussion and figure copied from preceding reference.)

Lingulella ampla (Owen), SCHUCHERT, 1897, Bull. U. S. Geol. Survey No. 87, p. 257. (Merely changes generic reference.)

Obolus (*Lingulella*) *amplus* (Owen), WALCOTT, 1898, Proc. U. S. Nat. Mus., vol. 21, pp. 392 and 394, Pl. XXVIII, figs. 3-4. (Mentioned in the text in discussion of *Lingulella*. The specimens represented by figs. 3 and 4 are redrawn in this monograph, Pl. XXVIII, figs. 1f and 1h, respectively.)

General form ovate, with the ventral valve obtusely acuminate and dorsal valve broadly ovate; valves moderately convex. Surface of shell marked by concentric striæ, and lines of growth and indistinct radiating striæ; very fine radiating striæ occur on the inner surface of the outer layer of the shell, and the casts show the presence of papillæ that indicate that the inner surface of the shell was punctate (Pl. XXVIII, fig. 1g). The shell is of medium thickness and formed of a thin outer layer and several inner layers or lamellæ which give a greater thickness to the posterior half. The lamellæ are arranged as in *Lingulella acutangula* (Roemer) where they are slightly oblique to the outer layer.

One of the larger ventral valves has a length of 18 mm., with a maximum width of 12 mm., and an associated dorsal valve has a width of 12 mm. and a length of 15 mm.

As shown in the cast of the interior of the shell, the area of the ventral valve is nearly flat near its lateral margin and rises from about the flexure line toward the pedicle groove. The pedicle furrow is shown by a narrow, elevated, rounded, tapering ridge which divides the area midway. The area is marked also by rather strong flexure lines which extend from the beak obliquely across the area at some distance from the outer margin, as shown in Plate XXVIII, figures 1c-f. The striæ of growth cross the area parallel with its base; they are very fine and closely grouped together on the lateral slopes; none of the specimens show their presence on the cast of the pedicle furrow. The area forms a thin shelf between the pedicle groove and the lateral margins, the undercut extending backward far under the area. This is well shown in several of the casts, although the cast of the undercut is usually broken away. A portion of it remains, however, in Plate XXVIII, figure 1c.

The area of the dorsal valve is well defined and is marked in one specimen by strong flexure lines (f, fig. 1h), and fine transverse striæ. As in the ventral valve, the area forms a thin shelf, the cast of the undercut extending well under the area in several of the specimens. Its ragged edges are shown in figure 1i.

The cast of the interior of the ventral valve shows the visceral cavity (v), and there are slight traces of a median septum (s) in the dorsal valve (Pl. XXVIII, fig. 1h). The muscle scars are partly preserved. In the ventral valve the anterior laterals (j) are shown in one cast (Pl. XXVIII, fig. 1c). The central, middle lateral, and outside lateral muscle scars are all crowded together and lost in the space in front of the anterior portion of the visceral cavity. The central (h) and anterior lateral (j) muscle scars are well defined in the dorsal valve (Pl. XXVIII, figs. 1g and 1h).

Of the markings left on the cast by the vascular system only the main sinus (vs) is preserved (Pl. XXVIII, figs. 1c, 1d, and 1f for the ventral valve and figs. 1g and 1h for the dorsal valve).

Observations.—One of the specimens illustrated by Owen [1852, Pl. I B, fig. 5] is in this monograph represented by Plate XXVIII, figure 1. It appears to be a ventral valve that

has been broken away toward the apex. His second figure [1852, Pl. I B, fig. 12] is a partially covered dorsal valve which shows the characteristic form and the concentric striæ of the species. His description [1852, p. 583] is as follows:

This species has a greater circumference and superficial area than any of the others hitherto discovered in F. 1. Shell nearly oval, rather flat; beak blunt, and not projecting beyond the general contour of the shell, and formed more after the manner of the beaks of *Terabratala*. A few faint concentric striæ. Length 11/16 of an inch; width 8/16 of an inch.

This species occurs in the *Lingula* and *Obolus* grits, member c, near Mountain Island, at the Dalles of the St. Croix, and elsewhere in Wisconsin.

James Hall did not have the type before him when he described the species. He identified a form from the lower bed at Trempealeau, which he regarded [1863, p. 125] as the typical form of the species. The original type came from Mountain Island, in the Mississippi just above the mouth of Trempealeau River. It also occurs at about the same horizon 10 miles lower down on the west shore of the river, opposite the mouth of Black River. In general form, this species somewhat resembles *Lingulella billingsiana* (Whiteaves) from Newfoundland, but it differs from that species in the character of the surface markings and that of the interior markings and scars, especially those of the dorsal valve. The position of the main vascular sinus of the dorsal valve distinguishes it from other species of which we have the interior markings. In a specimen of the ventral valve (Pl. XXVIII, fig. 1f) there appears to be a unique marking (y) in the central anterior portion of the valve. It recalls the heart-shaped pit (x) of *Obolus* and *Lingulella acutangula* (Roemer) (Pl. XVII, fig. 1f), but it is so far away from the normal position of that pit that it appears to be the result of a malformation or an impression in the cast which accidentally resembles the outline of the heart-shaped pit.

FORMATION AND LOCALITY.—Upper Cambrian: "St. Croix sandstone" at the following localities: (80) 0.66 mile (1.1 km.) southwest of the railway depot at Menomonie, Dunn County; (100) near Menomonie, Dunn County; and (98) near Eau Claire, Eau Claire County; all in Wisconsin.

Middle Cambrian: (84 and 84f) "St. Croix sandstone," at Dresbach opposite the mouth of Black River, Winona County; (84s) near Dakota, Winona County; and (339e) on Mountain Island, Minnesota, in Mississippi River just above the mouth of Trempealeau River; all in Minnesota.

(328g) Wisconsin shore of the Mississippi, near Trempealeau, Trempealeau County; and (328e) "St. Croix sandstone" at St. Croix Falls, Polk County; both in Wisconsin.

A closely related if not identical species occurs at the following locality. A ventral valve from this locality is illustrated in Plate XXVIII, figure 1j.

Middle Cambrian: (88a) Limestone about 100 feet (30.5 m.) above the quartzitic sandstone at the base of the Cambrian in the northern suburbs of Deadwood, Black Hills, South Dakota.

LINGULELLA ARGUTA (Walcott).

Plate XXIV, figures 5, 5a-b.

Lingula? manticula WHITE (in part), 1874, U. S. Geog. Surveys W. 100th Mer., Prelim. Rept. on Invertebrate Fossils, pp. 9-10. (Described as a new species, including specimens referred to both *Lingulella arguta* and *L. manticula*.)

Lingula? manticula WHITE (in part), 1877, U. S. Geog. Surveys W. 100th Mer., vol. 4, pp. 52-53, Pl. III, fig. 2a (not fig. 2b). (Described and discussed. The specimen represented by fig. 2a is redrawn in this monograph, Pl. XXIV, fig. 5. The specimen represented by fig. 2b is referred in this monograph to *Lingulella manticula*.)

Obolus (Lingulella) argutus WALCOTT, 1898, Proc. U. S. Nat. Mus., vol. 21, p. 396. (Described and discussed as below as a new species.)

General form ovate, with the ventral valve obtusely acuminate; valves moderately convex. Exterior surface of the shell unknown. Very fine radiating striæ and concentric lines of growth occur on the outer surface of the inner layer of the shell. The shell appears to be of medium thickness and formed of a thin outer layer and one or more thin inner layers or lamellæ. The type specimen of the ventral valve has a length of 6 mm. and a width of 4.5 mm.

Observations.—This species is founded upon one of the specimens illustrated by White [1875, Pl. III, fig. 2a] as *Lingula? manticula*. The broadly ovate form of the ventral valve clearly distinguishes it from that species. From the associated fragments of trilobites it evidently occurs at a lower horizon in the Middle Cambrian. A dorsal valve from the same locality

and in a slightly different character of limestone is illustrated and provisionally referred to the same species (Pl. XXIV, fig. 5a).

In outline this shell resembles *Lingulella bella* (Walcott) and *L. bellula* (Walcott) from Newfoundland; it is more broadly acuminate than these species and much smaller than *Lingulella bella*. It may also be compared with *L. punctata* (Walcott), from which it differs in being more ovate.

FORMATION AND LOCALITY.—Upper Cambrian: (313f) Limestone at Schellbourne, Schell Creek Range, White Pine County, Nevada.

Middle Cambrian: (3e) Thin-bedded limestone less than 400 feet (121.9 m.) above the quartzitic sandstones of the Cambrian, near Ophir, Oquirrh Range, Tooele County, Utah.

(11w) About 1,050 feet (320 m.) above the Lower Cambrian and 3,350 feet (1,021.1 m.) below the Upper Cambrian in the shales forming 1d of the Swasey formation [Walcott, 1908f, p. 182], at the head of Dome Canyon; (3w) about 2,350 feet (716.3 m.) above the Lower Cambrian, and 2,050 feet (624.8 m.) below the Upper Cambrian, in the central portion of the thin-bedded limestones forming 1c of the Marjum limestone [Walcott, 1908f, p. 180], in the cliff about 2 miles (3.2 km.) southeast of Marjum Pass; (10y) about 2,900 feet (884 m.) above the Lower Cambrian and 1,500 feet (457.2 m.) below the Upper Cambrian in the central portion of the limestone forming 1a of the Marjum limestone [Walcott, 1908f, p. 179], about 1 mile (1.6 km.) south-southwest of Marjum Pass; (3x and 11x) about 2,200 feet (670.6 m.) above the Lower Cambrian and 2,200 feet (670.6 m.) below the Upper Cambrian, in the limestones forming 1d of the Marjum limestone [Walcott, 1908f, p. 180], 2.5 miles (4 km.) east of Antelope Springs, in ridge east of Wheeler Amphitheater; and (11q and 11y) about 2,350 feet (716.3 m.) above the Lower Cambrian and 2,050 feet (624.8 m.) below the Upper Cambrian, in the limestones forming 1c of the Marjum limestone [Walcott, 1908f, p. 180], 2.5 miles (4 km.) east of Antelope Springs, in ridge east of Wheeler Amphitheater; all in the House Range [Walcott, 1908f, Pls. XIII and XV], Millard County, Utah.

(14m) Limestone about 7 miles (11.2 km.) south of Towner's ranch, Indian Creek, Lincoln County; (54) Eldorado limestone [Walcott, 1908f, p. 184], on the east slope of Prospect Mountain, in New York Canyon, Eureka district [Hague, 1892, Atlas, Eureka County; (59) limestone at the base of the western slope of Combs Peak, near the plain of Antelope Valley, Eureka district [Hague, 1892, Atlas], Eureka County; and (313e) limestone 2 miles (3.2 km.) west of Green's ranch, White Pine County; all in Nevada.

A shell which is provisionally referred to *Lingulella arguta* occurs associated with the latter species in the following locality:

Middle Cambrian: (313a) Limestone at Schellbourne, Schell Creek Range, White Pine County, Nevada.

LINGULELLA ATAVA (Matthew).

Plate XXXV, figures 5, 5a-h.

Leptobolus atavus MATTHEW, 1899, Bull. Nat. Hist. Soc. New Brunswick, vol. 4, pt. 3, No. 18, pp. 200-201, Pl. II, figs. 1a-b and d-f. (Described and discussed as a new species. The specimens represented by figs. 1a and 1d are redrawn in this monograph, Pl. XXXV, figs. 5 and 5c, respectively.)

Obolus (*Lingulepis*) *gregwa* WALCOTT (in part) [not (MATTHEW)], 1901, Proc. U. S. Nat. Mus., vol. 23, pp. 692 and 694. (Matthew's "*Leptobolus atavus*" mentioned as the young of "*Lingulepis gregwa*.")

Obolus (*Lingulella*) *atavus* (Matthew), WALCOTT, 1902, Proc. U. S. Nat. Mus., vol. 25, pp. 609-610. (Described and discussed essentially as below.)

Leptobolus atavus MATTHEW, 1903, Geol. Survey Canada, Rept. Cambrian Rocks Cape Breton, pp. 106-109, Pl. VI, figs. 2a-b and d-g. (Described and discussed. Figs. 2a-b, d-e, and g are copied from Matthew, 1899b, Pl. II, figs. 1a-b and d-f, respectively.)

General form elliptical, with the ventral valve subacuminate, and the dorsal valve broadly subacuminate in outline. In the shorter form of the valves the sides are almost uniformly rounded from the cardinal slopes to the frontal margin. The convexity of the valves is fairly strong, that of the dorsal valve being broken by a slight longitudinal flattening that extends from the posterior portion to the frontal margin. As shown by the matrix, the outer surface is marked by concentric ridges and fine striæ of growth. The interior cast shows concentric lines and traces of rather coarse radiating lines. None of the specimens preserve the shell, but from the strength of the interior surface markings it is inferred that the shell was rather thick.

The longest ventral valve in the collection has a length of 6 mm.; width, 3.5 mm. The dorsal valves are slightly shorter.

The area of the ventral valve is divided at the center by a strong pedicle furrow, and about midway between the pedicle furrow and the outer margin by clearly marked flexure

lines that extend from the apex, with a slightly outward curvature, to the base of the area. Striae of growth cross the area parallel with its base, being much stronger on the area than in the pedicle furrow. The area of the dorsal valve is fully as prominent as that of the ventral valve. It curves forward at the center and extends well out on the cardinal slopes. The flexure lines are clearly defined well out toward the lateral margin. The striae of growth cross the area parallel to the base.

The cast of the interior of the ventral valve shows only the outline of the visceral cavity, and that the main vascular sinuses extend a considerable distance in advance of the visceral cavity. The cast of the interior of the dorsal valve shows that it had a strong, broad, central ridge, divided by a faint longitudinal median sinus. Only traces have been seen of the main vascular sinuses.

Observations.—This is a very pretty little species that, in the absence of well-defined specimens, I [1901, p. 694] confused with the young of "*Lingulepis gregwa*" Matthew. Material collected by S. Ward Loper at the type locality, however, proves that the shell differs considerably from that of the young of *Lingulella (Lingulepis) gregwa*, although specimens of the dorsal valve of the two forms are often very much alike.

Matthew's illustrations [1903, Pl. VI, figs. 2a–b, d–g] of *Lingulella atava* are somewhat diagrammatic, as though they were drawn to represent the average form of several specimens. With the type specimens before me I find considerable variation in width and outline. Some have the outline of *Lingulella collicia* (Matthew) and the two types of the latter species are much like Matthew's figures of *Lingulella atava* [1903, Pl. VI, figs. 2a–b, d–g]. The specimens of *Lingulella collicia* have the rotund, subquadrate outline of *Lingulella atava* and not the uniform curvature of Matthew's figures of *Lingulella collicia* [1903, Pl. VI, figs. 3a, 3b]. With a large series of well-preserved material from the type locality and formation, I have endeavored to represent two forms that may be referred to *Lingulella atava* and *Lingulella collicia*, respectively. *Lingulella atava* is more slender and its sides are more uniformly curved than *L. collicia*, and it is also usually larger. *Lingulella cania* (Walcott) is a narrow, elongate form.

FORMATION AND LOCALITY.—Middle Cambrian: (10p) Sandstones just below the waterfall in Division E2b; (13d and 13d') sandstones opposite the third waterfall, between Divisions E2a and E2b; (131') sandstones of Division E3a; (344) sandy shales of Division E3b; (13n'' and 344b) sandstones of Division E3d; (13n')^a sandstones of Division E3e; and (13n and 344d) sandstones of Division E3f; all in Matthew's [1903, p. 21] Etcheminian, on Dugald Brook, Indian River, eastern Cape Breton, Nova Scotia, Canada.

LINGULELLA ATAVA INSULÆ (Matthew).

Plate XXXV, figures 8, 8a.

Leptobolus atavus insulæ MATTHEW, 1903, Geol. Survey Canada, Rept. Cambrian Rocks Cape Breton, pp. 110–112, Pl. VI, figs. 4a–c. (Described and discussed as a new variety. The specimens represented by figs. 4a and 4b are redrawn in this monograph, Pl. XXXV, figs. 8 and 8a, respectively.)

The form of this shell is much like that of *Lingulella cania* (Walcott) or a narrow *L. atava* (Matthew). The material representing it is not well preserved. Matthew [1903, Pl. VI, figs. 4a–c] has illustrated it with three somewhat diagrammatic figures that give his conception of its form and interior markings. I have figured two of the best preserved of the typical specimens. They show the general form and character to be similar to those of *L. atava*.

FORMATION AND LOCALITY.—Middle Cambrian: (307d [Matthew, 1903, p. 110]) Sandstones believed to belong to Division E2a of Matthew's Etcheminian, at Youngs (McFees) Point, George River, eastern Cape Breton, Nova Scotia.

LINGULELLA AUGA (Walcott).

Plate XXIV, figures 6, 6a–g.

Obolus (Lingulella) auga WALCOTT, 1898, Proc. U. S. Nat. Mus., vol. 21, pp. 396–397. (Described as below as a new species.)

General form subcuneate, with ventral valve obtusely acuminate, and the dorsal valve rounded acuminate; valves moderately convex. Surface of the shell, as indicated by casts

^a13n' is the type locality, though the specimens in the United States National Museum collections to which that number is assigned were collected later than the type specimens. Localities 344, 344b, and 344d are cited by Matthew (see pp. 268–269).

in the fine sandstone, marked by lines of growth, and fine, slightly undulating striæ; the inner surface is marked by somewhat irregularly scattered pits or punctæ, some of which are unusually large for the size of the shell. The few remaining traces of the shell indicate that it was relatively thin. The largest well-preserved cast of the ventral valve has a length of 5 mm., with a width of 4.5 mm. The dorsal valves are a little shorter, the length and breadth being nearly the same. Casts of the interior of the ventral valve show the presence of a rather long area divided midway by a narrow, clearly defined cast of a pedicle groove; traces of flexure lines are also preserved. The area of the dorsal valve is proportionately shorter than that of the ventral valve; traces of the visceral cavity (v) and the base of the main vascular sinuses (vs) are preserved in a few specimens and in one specimen the anterior lateral muscle scars appear to be present.

Observations.—In the form of the valves this species is somewhat similar to *Lingulella grandis* (Matthew) (Pl. XXXVIII); otherwise it appears to be quite distinct from any other described species. It has a long cardinal area and a narrow, deep pedicle furrow on the ventral valve.

FORMATION AND LOCALITY.—Middle Cambrian: (10a) Sandstones of the Rome formation, in west railroad cut through Shooks Gap; and (10b) limestones of the Rome formation at the western end of the central railroad cut through Shooks Gap; both in Bays Mountains, 10 miles (16.1 km.) southeast of Knoxville [Keith, 1895, areal geology sheet], Knox County, Tennessee.

LINGULELLA BELLA (Walcott).

Plate XIX, figures 2, 2a–q; Plate XXXVI, figure 4.

Obolus (*Lingulella*) *bellus* WALCOTT, 1898, Proc. U. S. Nat. Mus., vol. 21, pp. 397–398. (Described and discussed as a new species.)

Obolus (*Lingulella*) *bellus* WALCOTT (in part), 1901, Proc. U. S. Nat. Mus., vol. 23, pp. 685–687. (Described and discussed, including specimens now referred to *Lingulella concinna* Matthew and *L. lens* (Matthew).)

Obolus (*Lingulella*) *bellus* WALCOTT, MATTHEW, 1903, Geol. Survey Canada, Rept. Cambrian Rocks Cape Breton, p. 204. (Says "*O. (L.) bellus*" does not include "*Lingulella concinna*".)

General form ovate, with ventral valve obtusely acuminate, and dorsal valve broad ovate to ovate quadrate; valves moderately convex as far as can be determined from the somewhat compressed specimens as they occur in the sandy shales. The small ventral valves are more acuminate than the large ones and the smaller dorsal valves are more elongate. The change in form is slight from one to another specimen in the series, but the two extremes are so different that without the connecting series two species could be determined.

Surface of shell with numerous concentric lines of growth and fine radiating lines. The inner layers are marked by concentric lines and numerous fine radiating striæ.

The shell is relatively thin over the anterior portions and stronger near the cardinal margins. It is formed of a very thin outer layer, with one or more thin layers or lamellæ. The casts of the interior surface of the ventral valve show numerous papillæ arranged in concentric lines on the posterior half of the shell. These correspond to the punctæ of the inner surface.

A large ventral valve has a length of 22 mm.; width, 15 mm.; and a dorsal valve 18 mm. in length had a width of 14 mm. The specimens in the collection average from 2 to 3 mm. smaller than those measured.

The cast of the area of the ventral valve shows that it was rather long and extended well out onto the cardinal slope; it is divided midway by a strong pedicle furrow, and toward the lateral margin by a narrow flexure line. The area is marked by fine striæ of growth parallel to the margin. The area of the dorsal valve is rather short, but it extends laterally well out on the cardinal slopes. The shallow curve corresponding to the pedicle groove of the larger valve is wide and clearly defined.

The casts of the interior of the valves show almost no traces of the vascular markings or muscle scars. Only the central and anterior lateral muscle scars and the main vascular sinuses have been observed in the ventral valve.

Observations.—This fine species occurs in great abundance in the upper beds of Little Belle Island associated with a narrow form of *Lingula*; and also in the higher beds on Great Belle Island, and a little below the layers carrying *Obolus (Lingulobolus) affinis* (Billings) and *O. (L.) spissus* (Billings). The species is found at some little distance above the horizon in which I collected a species of *Olenus* and I refer the horizon to the Ordovician or the passage beds to the Ordovician fauna.

The species appears to be clearly distinct from any described form. It may be compared with *Lingulella davisii* (McCoy) in relation to its size and outline, but not in other respects. It differs in the size and position of the muscle scars and the more strongly punctate interior surface. Some of the smaller shells closely resemble *Lingulella concinna* Matthew and the larger ones *L. lens* (Matthew). When studying the material of the two latter forms in 1901, I referred them all to *Lingulella bella* [Walcott, 1901, p. 685], but with the large series now before me this reference is not sustained.

FORMATION AND LOCALITY.—Lower Ordovician: (114b) Sandstone 1 mile (1.6 km.) north of Lance Cove, Great Belle Island, Conception Bay, Newfoundland.

Upper Cambrian: (114 and 114a) Uppermost sandstone beds and the sandy shales underlying them on Little Belle Island, in Conception Bay, Newfoundland.

(343b) Limestone pebble on Sachuset Beach, near Newport, Narragansett Bay, Rhode Island.

LINGULELLA BELLULA (Walcott).

Plate XIX, figures 1, 1a-e.

Obolus (Lingulella) bellulus WALCOTT, 1898, Proc. U. S. Nat. Mus., vol. 21, p. 398. (Described and discussed as below, as a new species.)

Obolus (Lingulella) bellulus Walcott, MATTHEW, 1903, Geol. Survey Canada, Rept. Cambrian Rocks Cape Breton, p. 205. (Says this species and "*Lingula billingsiana*" Whiteaves are the same.)

General form ovate with the ventral valve obtusely acuminate; dorsal valve round ovate; valves moderately convex. Surface of shell marked by concentric lines of growth and exceedingly fine, irregular striæ that give the same appearance to the surface as that seen on *Obolus (Westonia) ella* (Hall and Whitfield), *Obolus fragilis* (Walcott), and on a larger scale on *Lingulella radula* Matthew. The outer layer of the shell usually adheres to the arenaceous matrix, leaving the shiny inner layer on the shell; this is marked by concentric striæ and lines of growth, and fine radiating striæ. The shell is thin and formed of a very thin outer layer and one or more thin inner layers or lamellæ.

The average length of the ventral valve is from 4 to 5 mm.; width, 3 to 3.5 mm. The dorsal valves are a little shorter, 0.5 mm. to 1 mm.

The cast of the area of the ventral valve shows it to be elongate, divided midway by a narrow but strong pedicle furrow, and, about midway between the pedicle furrow and the lateral margin, by a narrow flexure line; it is marked by striæ of growth parallel to its base. The area of the dorsal valve is not well shown on the specimens in the collection.

The cast of the interior of the ventral valve shows somewhat imperfectly the visceral cavity, but not the muscle scars. In an interior of the dorsal valve the main vascular sinuses (vs) are well shown (Pl. XIX, fig. 1d), also the median septum (s). The central muscle scars are faintly shown in one fragmentary interior of the dorsal valve.

Observations.—This beautiful little species occurs in the arenaceous shales and thin-bedded sandstones of Little Belle Island, in association with the larger species *Lingulella bella* (Walcott). It is closely related to *Lingulella ferruginea* Salter, but differs somewhat in form and the more anterior position of "the visceral cavity in the dorsal valve." The species is the Upper Cambrian representative of the Middle Cambrian species *L. ferruginea*. It occurs at about the same horizon as *L. billingsiana* (Whiteaves), but differs decidedly from it in form and convexity, the only points of comparison which the material permits.

FORMATION AND LOCALITY.—Upper Cambrian: (114 and 114a)^a Uppermost sandstone beds and the sandy shales underlying them on Little Belle Island, Conception Bay, Newfoundland.

^a 114a is the type locality.

LINGULELLA BILLINGSIANA (Whiteaves).

Plate XXIX, figures 3, 3a.

Lingula billingsiana WHITEAVES, 1878, Am. Jour. Sci., 3d ser., vol. 16, p. 226. (Described, see below, as a new species.)

Lingulella? *billingsiana* (Whiteaves), SCHUCHERT (in part), 1897, Bull. U. S. Geol. Survey No. 87, p. 256. (Merely changes generic reference and spelling of Whiteaves's *Lingula billingsiana*, cited above. Includes also reference to specimens now referred to *Lingulella grandis*.)

Not *Lingula billingsiana* Whiteaves, MATTHEW, 1903, Geol. Survey Canada, Rept. Cambrian Rocks Cape Breton, p. 205. (Mentions "*Obolus* (*Lingulella*) *bellulus*" Walcott as the same as "*Lingula billingsiana*."')

The original description by Whiteaves follows:

Shell small, very slightly convex, compressed at the sides; outline elliptic ovate, narrowest behind; length nearly twice the width; margin of the valves widening convexly and gradually from the beaks to the center, or a little beyond it; front narrowly and evenly rounded. Surface marked by fine concentric striations and faint radiating lines. Internal markings unknown. Length, about two lines and a half; width, one line and a half.

Observations.—Through the courtesy of Prof. J. F. Whiteaves I have been able to study the type specimens of this species. Much to my surprise I find them to be distinct from the forms (*Lingulella bella* and *L. bellula*, Pl. XIX) I collected on Little Belle Island and Great Belle Island, Conception Bay, and those (*Lingulella grandis* (Matthew), Pl. XXXVIII) tentatively compared with the species by Matthew. The shell is more elongate and convex than that of *Lingulella bella* (Walcott). Two specimens of the ventral valve are illustrated (Pl. XXIX, figs. 3 and 3a). No dorsal valves occur in the material available for study.

The outer surface is exfoliated from all of the specimens so as to show the shiny surface of the inner layer described by Whiteaves [1878, p. 226]. One of the broken ventral valves shows a narrow pedicle groove.

The specific name was given in honor of Mr. E. Billings.

FORMATION AND LOCALITY.—Upper Cambrian: (314a [Whiteaves, 1878, p. 226]) Shales on Kelleys Island, Conception Bay, Newfoundland.

LINGULELLA BORNEMANNI (Walcott).

Plate XXX, figures 18, 18a-c.

Lingula attenuata BORNEMANN [not SOWERBY], 1891, Nova Acta Acad. Cæs. Leop.-Carol. Germanicæ Naturæ Curiosorum, Bd. 56, No. 3, pp. 437-438, Pl. XIX (XXXIV), figs. 1-10. (Described and discussed in German, see below for liberal translation. Figs. 10a, 4, 8, and 7 are reproduced in this monograph, Pl. XXX, figs. 18, 18a-c, respectively.)

Obolus (*Lingulella*) *bornemanni* WALCOTT, 1901, Proc. U. S. Nat. Mus., vol. 22, pp. 687-688. (Described and discussed essentially as below as a new species.)

The original description by Bornemann follows:

Shell oblong oval, sharply pointed toward the beak, marked with fine concentric stripes which are usually regular, and also often marked with large, irregular, concentric folds. Faint radial or longitudinal striation usually appears distinctly on the surface in the center of the shell. At the vertex there is usually a distinct, straight, longitudinal impression.

Shape exceedingly variable, often unsymmetric, short rounded-triangular or almost circular, or narrower and elongated, more or less arched or even flat. The long-extended specimens resemble *Lingulella* (*Lingulepis*) *acuminata* (Conrad); others agree perfectly with Murchison's original figures of *Lingula attenuata*; others again may be compared with *Lingulella davisi* (McCoy) and were at first placed with that species. The simultaneous occurrence in enormous multitudes and the numerous transition stages leave no doubt that all these forms belong to one species, and the average type of them fits best to *Lingula attenuata* Sowerby.

Size, 2 to 9 mm.

The state of preservation is best in the slates, yet there the specimens are mostly pressed flat. The specimens existing in great numbers in the sandstones often still exhibit their original arching, but the delicate shells are ordinarily distorted in an irregular manner and poorly preserved.

Bornemann [1891, p. 437] identified this species with *Lingula attenuata* Sowerby, on account of the resemblance in outline of many of the specimens. Other specimens closely resemble *Lingulella* (*Lingulepis*) *acuminata* (Conrad) from the Middle and Upper Cambrian of North America. It is so improbable that a species of this character should persist from Middle Cambrian time to Middle Ordovician time that, notwithstanding the resemblance, I think it is better to

distinguish it from *Lingula attenuata* Sowerby [Davidson, 1866, p. 44] and give a specific name that will not lead to erroneous stratigraphic correlations. The Cambrian fauna of Sardinia is so distinct from that of other localities and the stratigraphic succession of the subfauna is so confused that I think it unwise to identify its species with described species unless the material is so full and well preserved that there is no doubt of their specific identity.

The specific name was given in honor of Dr. J. G. Bornemann.

FORMATION AND LOCALITY.—Middle? Cambrian: (354) Yellowish-brown slates not far from the buildings of Canal Grande; (354a) grayish-white quartzitic sandstone in the valley of Guttururu Sartu; (354b) yellowish sandstone with *Archæocyathus* at Punta Pintau and elsewhere; all [Bornemann, 1891, p. 438] in the island of Sardinia, Italy.

LINGULELLA BUTTSI Walcott.

Plate XXIX, figures 4, 4a-b.

Lingulella buttsi WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 3, pp. 70-71, Pl. VIII, fig. 6. (Described and discussed as below as a new species. Fig. 6 is copied in this monograph, Pl. XXIX, fig. 4.)

General form elongate ovate, with the ventral valve bluntly acuminate and the dorsal valve a little more rounded on the posterior margin. Both valves rather strongly convex. The greatest convexity of the dorsal valve is at the umbo, and of the ventral valve along the central section. A ventral valve 12 mm. in length has a convexity of 2 mm., and a dorsal valve 8 mm. long arches 1.75 mm. above the plane of the margin. A narrow, median, slightly flattened, almost concave space that extends from the apex to the front margin occurs on the dorsal valve. The exterior surface of the shell is dull dark-bluish gray and the inner layers shiny bluish black. The outer surface is marked by concentric striæ and lines of growth with a few indistinct radiating striæ; the striæ on the dorsal valve bend slightly backward where they cross the median, flattened space. The inner layers have many concentric striæ, also numerous fine radiating striæ. The shell is built up of several layers or lamellæ, so as to be strong in the umbonal region and thin toward the edges.

The largest ventral valve in the collection has a length of 12 mm. and a maximum width of 9.5 mm. at the anterior third of its length; a dorsal valve 10 mm. long has a width of 7 mm.

A partly exfoliated ventral valve indicates the presence of a strong ridge on each side of the visceral area somewhat similar to that in *Lingulella acutangula* (Roemer) (Pl. XVII).

Observations.—This fine shell has the general outline of the group of small shells of which *Lingulella ferruginea* Salter is typical. It differs from them in its large size and strong shell. All of the larger species of *Lingulella* are either more acuminate or broader in outline.

The material was collected by Mr. Charles Butts, of the United States Geological Survey, and I take pleasure in naming the species after him.

FORMATION AND LOCALITY.—Middle Cambrian: (90b) Conasauga limestone in cut on Louisville and Nashville Railroad, near Woodstock; and (90c) *Conasauga limestone near Kimbrel*; both in Bibb County, Alabama.

LINGULELLA CANIA (Walcott).

Plate XXXV, figures 3, 3a-d.

Obolus (Lingulepis) gregwa WALCOTT (in part) [not (MATTHEW)], 1901, Proc. U. S. Nat. Mus., vol. 23, p. 694. (Specimens now referred to *Lingulella cania* are here mentioned as representing the young of *Lingulella (Lingulepis) gregwa*.)

Obolus (Lingulella) canius WALCOTT, 1902, Proc. U. S. Nat. Mus., vol. 25, pp. 610-611. (Described as below as a new species.)

Shell small. General form elongate oval, with the ventral valve slightly acuminate. In both the ventral and dorsal valve the shell narrows posteriorly, the front being broadly rounded. The convexity of the two valves is well marked, and it is nearly the same in each.

Surface of the shell marked by fine concentric striæ and a few lines of growth. When the outer shell is exfoliated fine radiating striæ cross the fine concentric striæ. The shell appears to be of moderate thickness and formed of several thin layers or lamellæ. The largest ventral valve in the collection has a length of 5 mm.; width, 3 mm.; and a dorsal valve 4 mm. in length has a width of 2 mm.

The area of the ventral valve is elongate, being nearly one-fifth the length of the shell. It is divided midway by a very distinctly defined pedicle furrow. The flexure line is just perceptible about half the distance out from the pedicle furrow to the lateral margin.

The area extends well forward on the cardinal slopes and is marked by strong striae of growth parallel to its base. The area of the dorsal valve is shorter than that of the ventral, and is marked by fine lines of growth and clearly marked flexure lines that extend from the apex forward on a line with the main vascular sinuses.

The cast of the interior of the ventral valves shows a general outline of the visceral cavity and the main vascular sinuses. Only the base of the main vascular sinus has been seen in the dorsal valve.

Observations.—This very pretty little species occurs in association with *Paradoxides*. In my first study of the brachiopods collected by S. Ward Loper from Cape Breton I confused it [1901, p. 694] with the young of *Lingulella (Lingulepis) gregwa* (Matthew). By means of a larger collection made by Loper in 1901, I have been able to separate it from the young of the associated *Lingulella (Lingulepis) exigua* (Matthew) and from somewhat similar species that occur at a lower horizon, *Lingulella atava* (Matthew) and *L. collicia* (Matthew). It differs from both the latter species in having a more elongate oval outline. It differs from the young of *Lingulella (Lingulepis) gregwa* in being more regularly oval and in having the posterolateral margin curved instead of nearly straight.

FORMATION AND LOCALITY.—Middle Cambrian: (3i) Compact, fine-grained, thin-bedded, gray sandstone of the *Paradoxides* zone, on McLeans Brook, 1 mile (1.6 km.) east of McCodrum Brook and 1.5 miles (2.4 km.) west of Marion Bridge; and (10s) sandstone on McLeans Brook, near Marion Bridge; both in eastern Cape Breton, Nova Scotia, Canada.

LINGULELLA CEDENS (Barrande)

Plate XXX, figure 8.

Lingula cedens BARRANDE, 1868, Faune silurienne des environs de Hof, en Bavière, p. 102, fig. 66. (Described in French. Fig. 66 is copied in this monograph, Pl. XXX, fig. 8.)

Lingula cedens BARRANDE, 1868, Neues Jahrb. für Mineralogie für 1868, pp. 691–692, unnumbered plate, fig. 66. (Copy of preceding reference.)

This is one of the larger shells of the fauna at Hof, but as it is deformed by pressure it is difficult to give its specific characters. The author states that the surface of the internal cast contains traces of rather strong concentric striae, with finer intermediate striae; also traces of very fine longitudinal striae. Length, 18 mm.; greatest width, 12 mm.

Barrande [1868a, p. 102] compares this form with *Lingulella davisi* (McCoy), from which it appears to be very little different. It is probable that an extended series of specimens would unite it with *Lingulella wirthi* (Barrande).

FORMATION AND LOCALITY.—Passage beds between the Upper Cambrian and the Ordovician: (303c [Barrande, 1868a, p. 102]) *Suburbs of Hof*; and (303f [Pompeckj, 1896a, pp. 7 and 8]) railway cut near Schellenberg, a little distance back of the railway station at Neuhof, near Hof; both in Bavaria, Germany.

LINGULELLA CLARKEI n. sp.

Text figures 42A–D, page 486.

The ventral valve of this species has the same general outline and form as that of *Lingulella acutangula* (Roemer) (Pl. XVII, figs. 1, 1a, 1g) except that it is a little broader across the front. The dorsal valve differs materially in being proportionally narrower on the posterior half and in having a broad shallow sinus extending from the umbo to the front margin. A similar sinus occurs on one dorsal valve of *Lingulella manticula* (White) (Pl. XX, fig. 1a) and on all dorsal valves of *Obolus (Fordinia) perfectus* Walcott (Pl. LXIII, fig. 10b).

The largest ventral valve has a length of 9 mm.; width, 7 mm. A broad dorsal valve has a length of 5 mm.; width, 4.25 mm.

The exterior surface is marked by very fine concentric striæ or fine ridges of growth; numerous radiating striæ occur on the inner layers of the shell. Nothing is known of the interior of either valve.

The specific name is given in honor of Prof. J. M. Clarke, of Albany, New York.

FIGURE 42.—*Lingulella clarkei* n. sp. A, A', Exterior and side outline of ventral valve (U. S. Nat. Mus. Cat. No. 51853a). B, Exterior of ventral valve, the type specimen (U. S. Nat. Mus. Cat. No. 51853b). C, Broad form of dorsal valve (U. S. Nat. Mus. Cat. No. 51853c). D, Dorsal valve with exterior layer of shell exfoliated (U. S. Nat. Mus. Cat. No. 52458a).

The specimens represented by figures 42A, 42B, and 42C are from Locality 58; that represented by figure 42D is from Locality 60; both in Nevada.

FORMATION AND LOCALITY.—Middle Cambrian: (60) Limestone in the upper beds of the Secret Canyon shale, across the canyon from the dump of the old Richmond mine shaft; and (58) shaly limestones in the upper part of the Secret Canyon shale, east side of New York and Secret canyons; both in the Eureka district [Hague, 1892, Atlas], Eureka County, Nevada.

LINGULELLA COLLICIA (Matthew).

Plate XXXV, figures 1, 1a-f, 2, 2a-d.

Leptobolus? collicia MATTHEW, 1899, Bull. Nat. Hist. Soc. New Brunswick, vol. 4, pt. 3, No. 18, p. 200, Pl. I, figs. 3a-e. (Described as a new species. Figs. 1, 1a-b, Pl. XXXV, of this monograph are drawn from three of Matthew's specimens, but closer identification is impossible.)

Obolus (Lingulella) collicia (Matthew), WALCOTT, 1902, Proc. U. S. Nat. Mus., vol. 25, p. 610. (Characterized.)

Leptobolus collicia MATTHEW, 1903, Geol. Survey Canada, Rept. Cambrian Rocks Cape Breton, pp. 112-113, Pl. VI, figs. 3a-e. (Described and discussed. Figures copied from Matthew, 1899b, Pl. I, figs. 3a-e.)

Leptobolus collicia collis MATTHEW, 1903, idem, pp. 114-115. (Characterized as a new variety.)

This shell is associated with *Lingulella atava* (Matthew), but differs from that species in being larger and in having a more acuminate and broader ventral valve and more broadly oval dorsal valve. The exterior surface is marked by very fine, slightly irregular, concentric striæ. The variety *collis* is simply a wide form, that is so closely united to *L. collicia* by many gradations among the shells before me that I do not think it worthy of a distinct name.

FORMATION AND LOCALITY.—Middle Cambrian: (10p) Sandstones just below the waterfall in Division E2b; (13d') sandstones opposite the third waterfall in Dugald Brook, between Divisions E2a and E2b; (344a [Matthew, 1903, p. 26]) sandy shales of Division E3c; (13n')^a sandstones of Division E3c; (344d [Matthew, 1903, p. 82]) sandy shales of Division E3f; all in Matthew's [1903, p. 21] Etcheminian, Dugald Brook, Indian River, Cape Breton, Nova Scotia.

(13m) Sandstones of Division E3f in Matthew's Etcheminian, Gillis Brook, eastern Cape Breton, Nova Scotia.

(344e [Matthew, 1903, p. 78]) Shales of Division E1d of Matthew's Etcheminian, on Boundary Brook, eastern side of the Escasonie Indian Reservation, eastern Cape Breton, Nova Scotia, Canada.

LINGULELLA CONCINNA Matthew.

Plate XXXIII, figures 2, 2a-h; Plate XXXIV, figures 1, 1a-r.

Lingulella concinna MATTHEW, 1901, Bull. Nat. Hist. Soc. New Brunswick, vol. 4, pt. 4, No. 19, pp. 273-274, Pl. V, figs. 2a-b. (Described and discussed as a new species. Pl. XXXIII, fig. 2d, of this monograph is drawn from one of Matthew's specimens, but which one can not be determined.)

Obolus (Lingulella) bellus WALCOTT (in part), 1901, Proc. U. S. Nat. Mus., vol. 23, p. 685. (Matthew's *Lingulella concinna* is referred to, and described with *Lingulella bella*.)

Obolus (Lingulella) concinnus (Matthew), WALCOTT, 1902, idem, vol. 25, pp. 608-609. (Described and discussed somewhat as on p. 487.)

^a 13n' is the type locality, though the specimens in the United States National Museum collections to which that number is assigned were collected later than the type specimens.

Lingulella concinna MATTHEW, 1903, Geol. Survey Canada, Rept. Cambrian Rocks Cape Breton, pp. 203-204, Pl. XIV, figs. 5a-b. (Description and figures copied from Matthew, 1901a, p. 273, Pl. V, figs. 2a-b.)

General form ovate. Ventral valve obtusely acuminate; dorsal valve broad, rounded ovate; valves moderately convex. Surface of shell marked with numerous concentric lines of growth and with intervening bands of striæ that are somewhat undulating. When the outer surface of the shell is exfoliated the shiny inner layers of the shell are marked by both concentric and radiating striæ.

The shell is thin and formed of a thin outer layer, and several thin inner layers or lamellæ. In some of the layers of argillaceous shale the shell has a bluish tinge with a glistening surface, often wrinkled and ridged by longitudinal compression and also compressed into transverse ridges when the shell has been distorted by movement in the shale. In some of the specimens in the sandy layers, a few concentric lines of minute punctæ occur on the posterior portion of the inner surface. A large ventral valve has a length of 15 mm. with a width of 10 mm., and a dorsal valve 11 mm. in length has a width of 8 mm. The average length of several hundred specimens of the ventral valve is from 6 to 7 mm.

The cast of the area of the pedicle valve shows it to be rather long and well extended out on the cardinal slopes. A clearly defined pedicle furrow divides it midway, and a narrow flexure line occurs about halfway between the pedicle furrow and the outer margin. The area is marked by fine striæ of growth parallel to the margin. The area of the brachial valve is short and seldom well preserved.

The cast of the interior of the valves, both in the argillaceous and sandy shale, shows almost no traces of vascular markings or muscle scars.

Observations.—When studying this species in 1901 I had a few specimens which at the time I considered to be identical with *Lingulella bella* (Walcott). During the season of 1901 S. Ward Loper collected many hundred specimens on McNeil Brook, and other localities in Cape Breton, that clearly showed that Matthew [1901a, p. 273] was correct in assigning it to a distinct species. I was not sure that his *Lingulella lens* (Matthew) was distinct, as the material from which he described and figured it was badly crushed and broken, the fragments of shell being embedded together in the limestone. None of the typical specimens show the apex of the ventral valve. The one used in illustration by Matthew [1901a, Pl. V, fig. 3a] has all the apex broken away, and the shell is somewhat compressed laterally. A photograph of this specimen of *Lingulella lens* (Matthew) is reproduced in Plate XXXIII, figure 1.

Among the collections made by Loper, there are a large number of shells crushed and crowded together very much as in the typical material of *Lingulella lens* used by Matthew. There are, however, in the accompanying shales large numbers of individual specimens which are beautifully preserved, which illustrate the outline and convexity of the shell. The series illustrates the growth of the shell, also the various forms in which it occurs owing to the difference in sediment in which it has been embedded. The material collected by Loper came from several horizons of the Upper Cambrian. Matthew [1901a, pp. 273-274] assigns "*Lingulella concinna*" to the *Dictyonema* zone, and "*Lingula lens*" to the *Parabolina* zone.

The shells in the arenaceous shales on McAdam shore are clearly *Lingulella concinna*, but in the calcareous layers the shells are different and I retain the name *lens* for them.

I received from Dr. G. Lindström a specimen from the black *Dictyonema* shales of Skåne, Sweden, labeled "*Lingulella nathorsti* Linnarsson." This is evidently an accident, as that species occurs only in the Lower Cambrian and the specimen is a broader shell much like that of *L. concinna* of Cape Breton. With our present information it is provisionally referred to *L. concinna*.

FORMATION AND LOCALITY.—Upper Cambrian: (3h) Shale and shaly limestone on McNeil Brook, 1.5 miles (2.4 km.) east of Marion Bridge; (307 [Matthew, 1903, p. 204] shales of Division C3c of Matthew on McLeod Brook (=Barachois River); (10c) shales on west side of Barachois River; (10n) shale in ravine on east side of Barachois Glen, 3 miles (4.8 km.) from Barachois; (10e, 10f, 10g, and 10h) shale on small east branch of Barachois River, about 0.75 mile (1.2 km.) north of the crossroad from Boisdale to Upper Leitches Creek; (8d and 372) shale at Upper Leitches Creek; (10m and 372a) shale 2 miles (3.2 km.) south of the Boisdale Road from Upper Leitches Creek; (10d and 10i) shale in high bank on west side of Barachois River, just north of the Boisdale Road; (13h) shale on east bank of Barachois River, 1.5 miles

(2.4 km.) north of Boisdale; (101) shale on east bank of Barachois River, 6 miles (9.6 km.) from Little Bras d'Or Lake; (3q) shale in Barachois Glen, 4 miles (6.4 km.) south of Little Bras d'Or Lake; (3p and 372b) shale in ravine 0.5 mile (0.8 km.) north of McMullins, on the crossroad to Boisdale; (160) shales on McMullins Brook, in the east Boisdale district; (3o and 372c) shale in ravine east of the railroad, just south of Barachois; and (372d) shale on McAdam shore on East Bay, east of Bras d'Or Lake; all in eastern Cape Breton, Nova Scotia.

Middle Cambrian: (3i) Compact, fine-grained, thin-bedded, gray sandstone of the *Paradoxides* zone, on McLean Brook, 1 mile (1.6 km.) east of McCodrum Brook and 1.5 miles (2.4 km.) west of Marion Bridge, eastern Cape Breton, Nova Scotia.

A specimen from the following locality is provisionally referred to *Lingulella concinna*:

Upper? Cambrian: (310h) Shale collected somewhere (probably Fogelsång), in the old Province of Skåne, now the Provinces of Malmöhus and Christianstad, Sweden.

LINGULELLA CUNEOLA (Whitfield).

Plate XXVII, figures 7, 7a-b.

Lingulepis cuneolus WHITFIELD, 1877, U. S. Geog. and Geol. Survey Rocky Mtn. Region, Rept. Geology Black Hills of Dakota; Prelim. Rept., pp. 8-9. (Described and discussed as below as a new species.)

Lingulepis cuneolus WHITFIELD, 1880, U. S. Geog. and Geol. Survey Rocky Mtn. Region, Rept. Geology and Resources Black Hills of Dakota, by Newton and Jenney, p. 336, Pl. 11, figs. 5 and 6. (Description copied from preceding reference. The specimen represented by fig. 6 is redrawn in this monograph, Pl. XXVII, fig. 7.)

Obolus (Lingulella) cuncolus (Whitfield), WALCOTT, 1899, Mon. U. S. Geol. Survey, vol. 32, pt. 2, p. 443. (Merely changes generic reference.)

The original description by Whitfield follows:

Shells small, rather below the medium size, triangularly ovate in outline or sometimes subcuneate; ventral valve triangularly ovate, with a sharp somewhat pointed beak, the width and length about as three and four, and the point of greatest width near the lower third of the length of the valve; cardinal slopes abrupt, scarcely convex; basal line rounded at the sides, but nearly straight in the middle; surface of the valve strongly convex, becoming almost subangular in the upper part; dorsal valve much shorter proportionately than the ventral, the length but little exceeding the width; side and base more rounded and the beak truncate; surface distinctly convex.

Surface of the shell apparently smooth, but usually exfoliated, in which condition a few fine radiating lines are visible.

This shell differs from *L. pinnaformis* Owen in size and in the more distinctly cuneate form of the ventral valve. At first sight it might be taken for the young of that species, but a little critical examination soon reveals marked distinctions in the truncation of the front margin, and especially in the form of the cardinal slopes, which are rounded and never concave, as in almost all ventral valves of that species. In consequence of this latter feature the beak does not appear so attenuated as in that one, although proportionately quite as long. In the general surface characters and form of the valves it corresponds with the genus *Lingulepis*, although we have not been able to distinguish the muscular impressions.

Were it not for the difference in the size of the shells we should be inclined to think this might be the species figured by Messrs. Meek and Hayden [1865, p. 3, Pl. I, figs. 1a-b] as *Lingulepis dakotensis*; but as their figures appear to be of the natural size, we should suppose it to be very distinct, as all the specimens of our shell noticed have been small, none exceeding one-fourth of an inch in length.

Observations.—This species does not appear to be correctly referred to *Lingulepis*. In outline it resembles some of the cuneate forms of *Lingulella*, and in its thick laminated shell it approaches *Lingulella phaon* (Walcott) (Pl. XXVI). Like that species, it has a thick outer layer and strong, radially striated inner layers, and numerous lamellæ slightly oblique to the outer layer over the anterior portions of the shell, especially about the anterior and lateral margins. Most of the specimens are in the form of partial casts, only a portion of the outer shell adhering to the cast.

The form of the ventral valve approaches that of some of the broader shells of *Lingulella perattenuata* (Whitfield) (Pl. XXI). It differs, however, in being more cuneate. Except for the somewhat straighter slope of the sides toward the beak it might be identified with *Lingulella acutangula* (Roemer) (Pl. XVII). Although fairly large collections were made from the Cambrian formations in the Black Hills during the field season of 1897, no specimens were found that could be definitely identified as belonging to this species, the only material available for study being that in the original collections of W. P. Jenney.

FORMATION AND LOCALITY.—**Middle Cambrian:** (355) Sandstones in Red Canyon Creek, southwest side of the Black Hills, South Dakota.

Specimens somewhat doubtfully referred to this species occur at the following locality:

Middle Cambrian: (167) Sandstone beneath limestone and resting on the pre-Cambrian in a bluff 9 miles (14.4 km.) west of Custer, Black Hills, South Dakota.

LINGULELLA DAMESI (Walcott).^a

Plate XXXIX, figures 8, 8a-c.

Obolus (*Lingulella*) *damesi* WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 329. (Characterized as below as a new species.)

The general descriptions of *Obolus chinensis* (Walcott) (p. 387) and *Lingulella prima* (Hall) (p. 526) apply so closely to this species that it does not appear necessary to do more than call attention to the points in which they differ. From *Obolus chinensis* (Pl. XXXIX) this species varies in having a more elongate, acuminate ventral valve and a more ovate dorsal valve; the valves are also less convex. From *Lingulella prima* (Pl. XXVII) it differs in the more gradual curvature of the sides from the apex to the front margin, in this respect resembling some varieties of *L. ferruginea* Salter (Pl. XXIX). The average size of the ventral valve is about 5 mm. in length by 3.5 mm. in width.

The specific name was given in honor of Dr. W. Dames.

FORMATION AND LOCALITY.—**Middle Cambrian:** (C7) Lower limestone member of the Kiulung group [Blackwelder, 1907, pp. 37 and 39 (last list of fossils), and fig. 8a (bed 33), p. 29], 2.2 miles (3.5 km.) southwest of Yenchuang; and (C10) lower shale member of the Kiulung group [Blackwelder, 1907, pp. 37 and 40 (part of 3d list of fossils), and fig. 8a (bed 35), p. 29], about 3 miles (4.8 km.) southwest of Yenchuang; both in the Sintai district, Sbantung, China.

A shell which may be a variety of this species occurs at the following locality:

Upper Cambrian: (C64) Upper limestone member of the Kiulung group [Blackwelder, 1907, pp. 37 and 42 (first list of fossils), and fig. 10 (bed 20), p. 38], 2.7 miles (4.3 km.) southwest of Yenchuang, Sintai district, Shantung, China.

LINGULELLA DAVIDSONI (Barrande).

Plate XXXII, figures 1, 1a-e.

Lingula davidsoni BARRANDE, 1879, Système silurien du centre de la Bohême, vol. 5, Pl. CIV, figs. VIII: 1-4. (Not described, but figured as a new species. Pl. CIV, figs. VIII: 1A, 1b, 3A, 3b, 4E, and 4 are reproduced in this monograph, Pl. XXXII, figs. 1, 1a-e, respectively.)

In the absence of specimens for study an opinion of the generic relations of this fine species is necessarily based on the illustrations given by Barrande. Comparing Plate XXXII, figures 1 and 1b, with Plate XVII, figure 1a, we note at once the similarity between *Lingulella davidsoni* and *L. acutangula* (Roemer) in their general form and the character of their areas as far as shown for *Lingulella davidsoni*. Fragments of the exterior shell of the latter (Pl. XXXII, fig. 1b) may be compared with the exterior surface of the former (Pl. XVII, fig. 1). The dark oval spots in front of the area in figure 1d may be of importance, or they may represent only a depression on each side of the median ridge such as often occurs in compressed shells. If this species is a typical *Lingulella*, it is one of the last of its race, occurring as it does in Étage d4 of Barrande's section.

The specific name was given in honor of Thos. Davidson.

FORMATION AND LOCALITY.—**Ordovician:** (303m) Étage d4 at Lieben; (303n) Étage d4 at Wraž; and (303o) Étage d4 at Lodenitz; all [Barrande, 1879b, Pl. CIV] in Bohemia, Austria-Hungary.

LINGULELLA DAVISI (McCoy).

Plate XXX, figures 2, 2a; Plate XXXI, figures 6, 6a-h.

Lingula sp. DAVIS, 1846, Quart. Jour. Geol. Soc. London, vol. 2, pt. 1, p. 70. (Mentioned only.)

Not *Lingula ovata* MCCOY, 1846, Silurian Fossils of Ireland, p. 24, Pl. III, fig. 1. (Described and discussed. This species is not taken up in this monograph.)

^a Better preserved and more complete series of specimens of this species collected by Dr. J. P. Iddings, in Manchuria, indicate that the form bears a closer relationship to *Obolus* than to *Lingulella*. In the volume on Paleontology of Willis's work on Research in China (Carnegie Institution of Washington) the species will be described and figured under the title, *Obolus damesi* (Walcott).

- Obolus* (*Lingulella*) *davisii* (McCoy), WALCOTT, 1898, Proc. U. S. Nat. Mus., vol. 21, pp. 394 and 395, Pl. XXVII, figs. 1-5. (Mentioned in discussion of genus *Lingulella*. The specimens represented by figs. 1, 2, 4, and 5 are redrawn in this monograph, Pl. XXX, figs. 6f, 6d, 6e, and 6h, respectively.)
- Lingulella* cf. *davisii* (McCoy), MATTHEW, 1902, Bull. Nat. Hist. Soc. New Brunswick, vol. 4, pt. 5, No. 20, pp. 407-408. (Described.)
- Lingulella* cf. *davisii* (McCoy), MATTHEW, 1903, Geol. Survey Canada, Rept. Cambrian Rocks Cape Breton, p. 203. (Copied from preceding reference.)

The characters of this species, as far as known to me, are illustrated on Plate XXXI, and reference is made to some of them in the description of the genus *Lingulella*. Many interesting observations are given by Davidson [1866, p. 57] in his description of the species and its occurrence at various localities in Wales.

E. Kayser [1897, Pl. VII, fig. 6] illustrates a dorsal? valve from the Cambrian beds of Iruya, Province of Salta, Argentina, which he compares with *Lingulella davisii*. The specimen indicates the presence of a form that may be the representative of *L. davisii*, but it may be a new form, or possibly identical with some one of the species of the Atlantic basin fauna found in New Brunswick or Newfoundland. The original figure is reproduced on Plate XXX, figure 2.

The form illustrated by Kayser [1883, Pl. III, fig. 3] in the report on the Cambrian brachiopods of Liaotung is also suggestive of *Lingulella davisii*, as may be seen by comparing a copy of Kayser's figure on Plate XXX with the illustration of *L. davisii* on Plate XXXI, figure 2a.

It should also be compared with *Lingulella ampla* (Owen) (Pl. XXVIII, figs. 1, 1a-j) of the Mississippi Valley.

The specific name was given in honor of Mr. J. E. Davis, who first called attention to the species.

FORMATION AND LOCALITY.—**Ordovician**: (304n) "Coniston (Bala) limestone" [McCoy, 1854, p. 254], at Coniston, Lancashire, England.

Upper Cambrian: (366d) Lower *Lingula* flags at Carnedd Filiast, Bangor; (366e) Lower *Lingula* flags at Marchillyn-mawr, Llanberis; both [Davidson, 1866, p. 57] in Carnarvonshire, North Wales.

Lower *Lingula* flags at the following localities: (366f) Ffestiniog; (366g) Dolgelly; (366h) Pen-y-Bryn, 5 miles (8 km.) north of Dolgelly; (366i) Llyn Dywarchen; (366j) Pont Nant-y-Lladron, on the Bala Road; (366k)^b *Penmorfa*; (366l)^b *Tremadoc*; and (366m)^b near *Nant-y-Groes*, west of Bala; all [Davidson, 1866, p. 57] in Merionethshire, North Wales.

(366n) Lower *Lingula* flags at Portmadoc; (366o) "Bala schists" [McCoy, 1854, p. 254] at Bryn Melyn, near Bala; (366p [Davidson, 1866, p. 57]) Upper Tremadoc beds at Deudraeth; (366q [Davidson, 1866, p. 57]) Upper Tremadoc beds at Garth, opposite Portmadoc; and (366a) upper portion of Middle *Lingula* flags, 6 miles (9.6 km.) east of Ffestiniog; all in Merionethshire, North Wales.

(366r) Shale 2 miles (3.2 km.) north of Builth, Brecknockshire; and (366 [Davidson, 1866, p. 57]) at Whitesand Bay, near St. Davids Head, Pembrokeshire; both in South Wales.

(318m [Davidson, 1866, p. 57]) Near the base of the lower black slates, in the Waterfall Valley near Maentwrog, North Wales.

(307a [Matthew, 1903, p. 203]) Shales of Division C3c2 of Matthew on McLeod Brook (=Barachois River), near Boisdale, eastern Cape Breton, Nova Scotia, Canada.

(389d [Kayser, 1897, p. 280]) Iruya, Province of Salta, Argentina, South America.

(332 [Kayser, 1883, p. 35]) Limestones at Saimaki, Liaotung, China.

LINGULELLA DELGADOI n. sp.

Plate XXIX, figures 6, 6a-c.

Lingulepis acuminata meeki DELGADO [not WALCOTT], 1904, *Comunicações Comissão Serviço Geol. Portugal*, tome 5, fasc. 2, pp. 366-367, Pl. IV, figs. 17 and 27; Pl. VI, fig. 9. (Characterized and discussed in French. A photograph of the specimen represented by fig. 27 (reverse view) is reproduced in this monograph, Pl. XXIX, fig. 6b.)

Lingulella granvillensis DELGADO [not WALCOTT], 1904, *idem*, pp. 367-368, Pl. IV, figs. 15, 16, 18, and 19. (Discussed in French. Photographs of the specimens represented by figs. 16 and 18 are reproduced in this monograph, Pl. XXIX, figs. 6 and 6a, respectively.)

Lingulella ferruginea DELGADO [not SALTER], 1904, *idem*, pp. 368-369, Pl. IV, figs. 20 and 21; Pl. VI, fig. 2. (Discussed in French.)

Lingulella cf. *linguloides* Matthew, DELGADO, 1904, *idem*, pp. 369-370, Pl. IV, fig. 14. (Described and discussed in French. A photograph of the specimen represented by fig. 14 (reverse view) is reproduced in this monograph, Pl. XXIX, fig. 6c.)

This is one of the abundant and variable forms in the fauna of the Province of Alemtejo. It may be compared in this respect with the widely distributed *Lingulella ferruginea* Salter. Delgado compares different phases of it to three species, two of which, *L. ferruginea* Salter and *L. cf. linguloides* Matthew, I think are specifically the same. *Lingulella granvillensis* Walcott has the same flattening along the median line of the ventral valve. As stated by Delgado [1904, p. 367], there is a strong resemblance between the representatives of the two forms, but I think that it is better to give the Portuguese form a distinct specific name than to identify it with the American species.

Delgado sent me enlarged photographs of the specimens of the three varieties which he recognized and illustrated, and I have reproduced four of them, Plate XXIX, figures 6, 6a-c.

It is quite probable that if I had all of Delgado's specimens to study a different disposition would be made of the specific references, but with present knowledge and experience of the variability of species like this, especially where the shells have been more or less misshaped by lateral movement in the "schists," I prefer to combine the forms in one species.

The specific name is given in honor of the late Dr. J. F. Nery Delgado.

FORMATION AND LOCALITY.—**Lower Cambrian**: (351 [Delgado, 1904, pp. 366-369]) Shales at Monte de Valhom, northeast of Villa Boim, Province of Alemtejo, Portugal.

^a The species also occurs in Locality 317b (p. 248).

^b Davidson does not state which of the three localities (366k, 366 l, or 366m) is the type.

LINGULELLA DESIDERATA (Walcott).

Plate XX, figures 4, 4a-c, 5, 5a-j.

Obolus (Lingulella) desideratus WALCOTT, 1898, Proc. U. S. Nat. Mus., vol. 21, pp. 399-400. (Described and discussed as a new species.)

Obolus (Lingulella) desideratus WALCOTT (in part), 1899, Mon. U. S. Geol. Survey, vol. 32, pt. 2, pp. 445-446, Pl. LX, fig. 2 (not 2a). (Described essentially as below, and discussed. The specimen represented by fig. 2 is redrawn in this monograph, Pl. XX, fig. 4. The specimen represented by fig. 2a is referred in this monograph to *Obolus rotundatus*, Pl. XX, fig. 2e.)

Dicellomus nanus WALCOTT (in part) [not MEEK and HAYDEN], 1899, idem, p. 447, Pl. LX, fig. 3 (not figs. 3a-d). (Mentioned. The specimen represented by fig. 3 is redrawn in this monograph, Pl. XX, fig. 5j. The specimens represented by figs. 3a-d are referred in this monograph to *Dicellomus nanus*.)

Shell small, subovate, with the ventral valve obtusely acuminate, and the dorsal valve broadly ovate. Valves are strongly convex, with the ventral valve fully as much so as the dorsal. There is a slight variation in the outline of the valves, some being slightly more rounded posteriorly than others.

The surface of the shell is marked by fine, concentric lines of growth, and between them very fine, slightly irregular striæ; a few rather narrow indistinct undulations radiate from the umbo toward the front and lateral margins; when the outer shell is partly exfoliated the outer surface of the inner layer is marked by very fine indistinct radiating striæ; there are a few traces of small, scattered pits or punctæ on the inner surface. The shell is thin and formed of an outer layer and one or more inner layers or lamellæ.

The average length of the ventral valve is about 4 mm.; width, 3 mm. A dorsal valve 3.5 mm. long has a width of 3 mm.

A cast of the interior of a ventral valve shows an area of medium length, divided midway by a narrow, clearly defined pedicle groove. The area of the dorsal valve is short. Nothing is known of the interior of the ventral valve, but in a cast of a dorsal valve there are traces of the main vascular sinuses, central median septum, and the central muscle scars.

Observations.—This species may be compared with the Middle Cambrian *Lingulella ferruginea* Salter of the Atlantic basin faunas, and *L. similis* (Walcott), of the Black Hills, upper Mississippi Valley, and Appalachian faunas. *Lingulella similis* is more convex and narrower, and *L. manticula* (White) is considerably more acuminate. Compared with the Rocky Mountain species it is intermediate between *L. manticula* and *L. rotunda* (Matthew). It may also be compared with *L. granvillensis* Walcott of the *Olenellus* fauna of eastern New York, and *L. iole* (Billings) of the Lower Ordovician fauna of Newfoundland. It is distinguished from *L. granvillensis* by its more regularly rounded anterior margin.

The specimens represented by Plate XX, figures 4b, 4c, and 5j, are broader proportionately than the typical specimens represented by Plate XX, figures 4 and 4a, but they occur at the same geological horizon in the Eureka district, Nevada. What appears to be the same, or a closely related species, occurs in the upper beds of the Secret Canyon shale in the Eureka district, Nevada.

A form that appears to be identical occurs in considerable abundance in Alabama and Tennessee. The similarity in form between the specimens from Wyoming and Nevada, and those from Alabama and Tennessee is shown by Plate XX, figures 4, 4a-c, of the typical specimens, and Plate XX, figures 5, 5a-i, of their representatives in the Appalachian region. This similarity is even more striking when the specimens are compared directly with one another, and some allowance made for the fact that the Appalachian specimens have all been more or less compressed.

A small shell that appears to be identical with this species occurs in the red sandstone and argillaceous shale of the Lower Ordovician of Colorado. The specimens from Trout Creek, below Bergen Park, are much like those from the Gallatin Range in Montana and the same species of *Billingsella* is associated with them. At Cement Creek, 10 miles (16.1 km.) south-east of Crested Butte, Colorado, the shells occur in a fine conglomerate and coarse sandstone

associated with a species of *Bathyurus* much like that from the beds containing *Lingulella desiderata* at Trout Creek.

FORMATION AND LOCALITY.—**Lower Ordovician:** (360) Red siliceous limestone near Colorado Springs; (186) near line of contact between red and gray Ordovician limestones, in red siliceous limestone about 30 feet (9.1 m.) above the pre-Cambrian rocks, Williams Canyon, Manitou; (187) red siliceous limestone 105 to 122 feet (32 to 36.7 m.) above the pre-Cambrian rocks, 2 miles (3.2 km.) below Manitou Park Hotel; (360a) red siliceous limestone on west side of Trout Creek, below Bergen Park, 7 miles (11.2 km.) north-northwest of Manitou; all in El Paso County, Colorado.

(360b) Red siliceous limestone on Cement Creek, 3 miles (4.8 km.) north of Hot Springs, Ouray County; and (360c) red siliceous limestone about 10 miles (16.1 km.) southeast of Crested Butte, Elk Range; both in Colorado.

Upper Cambrian: (161) Limestone on the south side of West Gallatin (Gallatin) River, northwest of Hamilton, on the north side of the Gallatin Valley, Gallatin County, Montana.

(7x, 7y, and 7z) Limestone of the Emigrant formation [Turner, 1902, p. 265], about 2.5 miles (4 km.) southeast of the summit of Emigrant Pass, Silver Peak quadrangle (U. S. Geol. Survey), Esmeralda County; (8n) limestone about 500 feet (152 m.) up in the limestones east of Swallow Ranch, west side of Snake Range, 20 miles (32.2 km.) south of Osceola, White Pine County; (313) limestone 0.75 mile (1.2 km.) east-northeast of McGill post office, White Pine County; and (61) limestone in the Dunderberg shale [Walcott, 1908f, p. 184], a little south of the Hamburg mine, Eureka district [Hague, 1892, Atlas], Eureka County; all in Nevada.

(30h) About 350 feet (106.7 m.) above the Middle Cambrian and 2,950 feet (899.2 m.) below the top of the Upper Cambrian near the base of the arenaceous limestones forming 2a of the Orr formation [Walcott, 1908f, p. 177]; and (30j and 30k) 950 and 1,150 feet (289.6 and 350.5 m.) above the Middle Cambrian and 2,450 and 2,175 feet (746.8 and 662.9 m.) below the top of the Upper Cambrian, in the arenaceous shales and limestone forming 1e of the Orr formation [Walcott, 1908f, p. 176]; all on Orr Ridge, about 5 miles (8 km.) south of Marjum Pass, House Range [Walcott, 1908f, Pl. XIII], Millard County, Utah.

(15d)^a Thin-bedded blue limestone near Cave Spring on the east side of the Fish Spring Range, about 4 miles (6.4 km.) south of the J. J. Thomas ranch, Juab County; (34t) limestone 1.5 miles (2.4 km.) northwest of Wahwah Springs, about 80 feet (24.4 m.) below the highest point on the north side of the road at Cane Pass, Wahwah Mountains, Beaver County; (32g) about 2,575 feet (784.9 m.) above the Cambrian quartzitic sandstones in a blue limestone about 2 miles (3.2 km.) southeast of Muskrat Springs on the northwest face of Grantsville Peak, Stansbury Range, Tooele County; (54j) about 700 feet (213.4 m.) above the Middle Cambrian and 525 feet (160 m.) below the top of the Upper Cambrian in the arenaceous limestones forming 2c of the St. Charles formation [Walcott, 1908f, p. 192], in Blacksmith Fork Canyon, about 10 miles (16.1 km.) east of Hyrum, Cache County; all in Utah.

(5a and 54t) Limestones of the St. Charles formation [Walcott, 1908a, p. 6] about 250 feet (76 m.) above the Middle Cambrian on the north side of Twomile Canyon, near its mouth, 2 miles (3.2 km.) southeast of Malade, Oneida County, Idaho.

(93 and 93o) Shales and limestones at the base of the Knox dolomite near Jordan's, just below the ford on Cowan Creek, about 8 miles (12.8 km.) southeast of Center; (93a)^b same horizon as Locality 93 on Terrapin Creek road from Center to Amberson; (94o) same horizon as Locality 93, 0.25 mile (0.4 km.) beyond Givens Ford, on Cowan Creek, about 8 miles (12.8 km.) southeast of Center; and (94xx) same horizon as Locality 93 at Givens mill, on Cowan Creek, about 8 miles (12.8 km.) southeast of Center; all in Cherokee County, Alabama.

(361) Shaly limestone in suburb of Attalla, Etowah County, Alabama.

(96) Limestones near the ford on the Cedartown road, 1.5 miles (2.4 km.) south of Rome, Floyd County; and (362) shales in the Oothkalooga Valley, Bartow County; both in Georgia.

(107u and 107o) Limestones and shales at the base of the Knox dolomite, west of the top of Copper Ridge, near the Southern Railway cut, about 10 miles (16.1 km.) northwest of Knoxville [Keith, 1896b, areal geology sheet], Knox County, Tennessee.

(122a)^c Shale at the headwaters of Forgey Creek, northwestern part of the Greeneville quadrangle (U. S. Geol. Survey), Hawkins County, Tennessee.

Upper? Cambrian: (56) Limestone at Sierra Springs, eastern base of Lookout Mountain, Eureka district [Hague, 1892, Atlas], Eureka County, Nevada.

Middle? Cambrian: (313c) Limestone about 12 miles (19.3 km.) west-southwest of Alpha Station, Eureka County, Nevada.

Middle Cambrian: (57) Shaly Eldorado limestone [Walcott, 1908f, p. 184] at the 700-foot (213.4 m.) level of the Richmond mine, Ruby Hill [Hague, 1892, p. 43, and Pl. I, opposite p. 116]; (57b) limestones at the north end of Mineral Hill, just south of Ruby Hill [Hague, 1892, p. 43, and Pl. I, opposite p. 116]; (60) limestones in upper beds of Secret Canyon shale, across the canyon from the dump of the old Richmond mine shaft; and (58) shaly limestones in upper beds of Secret Canyon shale, east side of New York and Secret canyons; all in the Eureka district [Hague, 1892, Atlas], Eureka County, Nevada.

(313b) Limestone 3 miles (4.8 km.) north-northeast of Schellbourne, Schell Creek Range, White Pine County, Nevada.

^a This species also occurs at Locality 341 (p. 196).

^b The species is somewhat doubtfully identified from this locality.

^c This species also occurs at Locality 122 (p. 223).

(15x) Limestones near the middle of the Fish Spring Range, near the line between Juab and Tooele counties; and (15p) limestones near the north end of the Fish Spring Range, Tooele County; both in Utah.

(5b) Dark blue-gray Langston limestone [Walcott, 1908f, p. 198], just above the Cambrian quartzitic sandstones, on the north side of Twomile Canyon, near its mouth, 2 miles (3.2 km.) southeast of Malade, Oneida County; (59f) limestones immediately underlying the Spence shale member of the Ute limestone [Walcott, 1908a, p. 8], in a saddle north of the creek which flows into Mill Canyon from the west, about 5 miles (8 km.) west-southwest of Liberty and 15 miles (24.2 km.) west of Montpelier, Bear Lake County; and (55c and 163) Spence shale member of the Ute limestone [Walcott, 1908a, p. 8], about 50 feet (15.2 m.) above the Brigham quartzite and 2,755 feet (839.7 m.) below the Upper Cambrian, in a ravine running up into Danish Flat from Mill Canyon, about 6 miles (9.6 km.) west-southwest of Liberty and 15 miles (24.2 km.) west of Montpelier, Bear Lake County; all in Idaho.

(55e) Spence shale member of the Ute limestone about 100 feet (30.5 m.) above the Brigham quartzite [Walcott, 1908f, p. 197], at the mouth of the first small canyon south of Wasatch Canyon, east of Lakeview ranch, 5 miles (8 km.) north of Brigham, Boxelder County, Utah.

(311 and 54h) About 3,140 feet (957.1 m.) above the Brigham quartzite and 1,050 feet (320 m.) below the Upper Cambrian in the limestones forming 1a of the Bloomington formation [Walcott, 1908f, p. 194]; and (54i) about 500 feet (152.4 m.) above the Brigham quartzite and 3,700 feet (1,127.8 m.) below the Upper Cambrian in the Spence shale member of the Ute limestone [Walcott, 1908f, p. 197]; both in Blacksmith Fork Canyon, about 10 miles (16.1 km.) east of Hyrum, Cache County, Utah.

(302l) *Limestone in the Gallatin Range*; and (302b) limestone near Crowfoot Ridge, Gallatin quadrangle (U. S. Geol. Survey); both in Yellowstone National Park, Wyoming.

(5f) Limestones interbedded in the Wolsey shale [Weed, 1900, p. 285], in Meagher County on the road to Wolsey, about 4 miles (6.4 km.) south of the divide at the head of Sawmill Creek and 11 miles (17.7 km.) south of Neihart, Little Belt Mountains quadrangle (U. S. Geol. Survey), Cascade County, Montana.

(58l) About 1,830 feet (557.8 m.) above the Lower Cambrian in the limestone forming 3b of the Stephen formation [Walcott, 1908c, p. 238(7)], on the east side of Mount Stephen about 3,000 feet (914.4 m.) above the Canadian Pacific Railway track, 3.5 miles (5.6 km.) east of Field, British Columbia.

(88a) Limestone about 100 feet (30.5 m.) above the quartzitic sandstone at the base of the Cambrian, in the northern suburbs of Deadwood, in the Black Hills, South Dakota.

(9) Limestone on southeastern slope of ridge 1 mile (1.6 km.) north of the northwest corner of Harlan Knob, about 4 miles (6.4 km.) northeast of Rogersville [Keith, 1905, areal geology sheet]; (9a) same horizon as locality No. 9 in limestone on the south shore of Holston River at Melinda Ferry, 5 miles (8 km.) southwest of Rogersville [Keith, 1896a, areal geology sheet]; (101a and 101b) Rogersville shale near the schoolhouse, 3.5 miles (5.6 km.) southwest of Rogersville, on the road to Melinda Ferry; (103b) third limestone south of the ridge of sandstone in the Rome formation ("Town Knobs"), on the road from Rogersville to Dodson Ford, near the line between the Morristown and Greeneville quadrangles (U. S. Geol. Survey); and (121) Rogersville shale, road just east of Harlan Knob, 4 miles (6.4 km.) northeast of Rogersville [Keith, 1905, areal geology sheet]; all in Hawkins County, Tennessee.

(117) Shales on the road north from Greeneville, Greene County, Tennessee.

(369g) Shales at Bonnetterre, St. Francois County, Missouri.

(90b) Conasauga limestone, in cut on the Louisville and Nashville Railroad, near Woodstock, Bibb County; (16) Conasauga ("Coosa") limestone, Blountsville Valley, Blount County; and (139) limestone on Hokes Bluff road, north of the chert outcrop, 5 miles (8 km.) east of Gadsden, Etowah County; all in Alabama.

Specimens somewhat doubtfully referred to this species occur at the following locality:

Middle Cambrian: (107a) Shale in railroad cut in Bull Run, northwest of Copper Ridge [Keith, 1896b, areal geology sheet], 11 miles (17.7 km.) northwest of Knoxville, Knox County, Tennessee.

LINGULELLA DUBIA (Walcott).

Plate XXIV, figures 4, 4a.

Lingulella ella WALCOTT (in part) [not HALL and WHITFIELD], 1886, Bull. U. S. Geol. Survey No. 30, pp. 97-98, Pl. VIII, figs. 4b and 4c (not Pl. VII, fig. 2, or Pl. VIII, figs. 4, 4a, 4d, and 4e). (Original description, Hall and Whitfield, 1887, p. 232, copied and species described and discussed. The specimens represented by figs. 4b and 4c are redrawn in this monograph, Pl. XXIV, figs. 4 and 4a, respectively. The specimens represented by Pl. VII, fig. 2, and Pl. VIII, figs. 4, 4a, 4d, and 4e, are referred in this monograph to *Obolus* (*Westonia*) *ella*.)

Lingulella ella WALCOTT (in part) [not HALL and WHITFIELD], 1891, Tenth Ann. Rept. U. S. Geol. Survey, p. 607, Pl. LXVII, figs. 2c-d (not figs. 2, 2a-b). (Mentioned. Figs 2c and 2d are copied from Walcott, 1886b, Pl. VIII, figs. 4c and 4b, respectively. The specimens represented by figs. 2c and 2d are redrawn in this monograph, Pl. XXIV, figs. 4 and 4a, respectively. The specimens represented by figs. 2, 2a-b, and 2e are referred in this monograph to *Obolus* (*Westonia*) *ella*.)

Lingulella ella HALL and CLARKE (in part) [not HALL and WHITFIELD], 1892, Nat. Hist. New York, Paleontology, vol. 8, pt. 1, p. 58, fig. 20 (not figs. 19 and 21). (Mentioned in the text. Fig. 20 is copied from Walcott, 1891a, Pl. LXVII, fig. 2c. The specimens represented by figs. 19 and 21 are referred in this monograph to *Obolus* (*Westonia*) *ella*.)

Obolus (Lingulella) dubius WALCOTT, 1898, Proc. U. S. Nat. Mus., vol. 21, p. 401. (Described and discussed essentially as below as a new species.)

Lingulella genei PACK, 1906, Jour. Geology, vol. 14, No. 4, p. 295, Pl. I, figs. 3, 3a-b. (Described and discussed as a new species.)

This is a small shell associated with *Obolus (Westonia) ella* (Hall and Whitfield). It occurs in the form of casts in argillaceous shale, no traces of the shell substance remaining. The ventral valve averages about 3 mm. in length, and the dorsal valves are a little shorter. A cast of the interior of the ventral valve shows the visceral cavity (v), and an unusually strong main vascular sinus (vs) on each side. Only one specimen shows these characters as illustrated by Plate XXIV, figure 4; others only faintly indicate them.

This dorsal valve is rounded ovate, and the cast of its interior shows a very short area that extends well out on the cardinal slopes. The interior markings are a portion of the main vascular sinuses, which, in their form and extension, somewhat resemble those of the dorsal valve of *O. (W.) chuarensis* (Walcott). The only muscle scars preserved are the anterior laterals of the dorsal valve.

As far as can be determined from the casts, the outer surface is marked by lines of growth and fine, slightly undulating concentric striæ.

Observations.—At first I thought the specimens now referred to this species were the young *Obolus (Westonia) ella*, and so illustrated them [1891a, Pl. LXVII, figs. 2c and 2d]. There is still considerable doubt as to their specific relations, but in view of the very distinct interior markings I have referred them to a new species.

The form described by F. J. Pack [1906, p. 295] as "*Lingulella genei*" comes from the same locality and band of shale as *L. dubia*, and has the same form and strong interior markings. Some of Pack's specimens show the cast of the exterior surface. This is marked by the very fine, concentric, slightly undulating lines so typical of *Lingulella*. The best-preserved casts of the surface do not present the characteristics of the surface of *Obolus (Westonia) ella*.

FORMATION AND LOCALITY.—Middle Cambrian: (31) Shales at the Chisholm mine, southwest slope of Ely Mountains; and (333 [Pack, 1906, p. 295]) shales on the dump of the Abe Lincoln mine; both near Pioche, Lincoln County, Nevada.

LINGULELLA ELLSI (Walcott).

Plate XIX, figures 3, 3a-c.

Obolus (Lingulella) ellsii WALCOTT, 1898, Proc. U. S. Nat. Mus., vol. 21, p. 402. (Described and discussed as below as a new species.)

Shell small, broad ovate in outline, with the ventral valve obtusely acuminate, and the dorsal valve broadly rounded; valves appear to have been moderately convex, judging from their appearance in the siliceous shale. The surface of the shell is marked by rather strong, concentric lines and striæ of growth, the striæ apparently indicating a slightly lamellose surface; very fine radiating striæ occur on the surface of the inner layers of the shell. A ventral valve 3.5 mm. in length has a width of 2.75 mm.; the dorsal valve is a little shorter than the ventral valve.

Partial casts of the interior of the ventral valve show a very clearly defined area that extended as a shelf on each side of the rather deep, narrow, pedicle furrow; portions of the casts that fill the undercut may be observed in several specimens; the flexure lines are narrow, sharp, and situated well out toward the lateral margins. The cast of the visceral area of the ventral valve extends about one-third the distance from the area to the anterior margin; it is not well defined, and no traces of muscle scars have been detected; of the vascular system only the base of the main sinuses is shown in any of the casts.

Observations.—This very pretty little species is closely related in form to *Lingulella rotunda* (Matthew), and comparison should also be made with the more rotund variety of *L. ferruginea* Salter. It occurs in association with *Acrothele pretiosa* (Billings).

The specific name is given in honor of Dr. R. W. Ells, whose fine work on the geology of a portion of the Province of Quebec unraveled the stratigraphic relations of the Lauzon slates in which the species occurs. Doctor Ells guided me to the locality at which the species occurs.

FORMATION AND LOCALITY.—Ordovician: (220a) Shales of the "Upper Sillery" (Lauzon of Logan), on Chaudiere River at the Grand Trunk railroad bridge, Province of Quebec, Canada.

Leptobolus gemmulus MATTHEW, 1903, idem, pp. 190-192, Pl. XIV, figs. 1a-c. (Original description, Matthew 1892, p. 41, copied, revised, added to, and discussed.)

Leptobolus cf. *linguloides* MATTHEW, 1903, idem, pp. 192-193. (Copy of Matthew, 1902b, p. 407.)

Leptobolus linguloides MATTHEW, idem, p. 193. (Merely changes generic reference.)

The original description by Salter [Salter and Hicks, 1867, p. 340] is as follows:

Length fully 2.5 lines. Form ovate-oblong, the front rather obtuse, but not straight edged; the sides nearly parallel; the obtusely pointed beak includes an angle of about 75°. Generally convex, especially down the median area; the sides beveled obliquely; the surface concentrically and very finely striated; the inner surface rather coarsely sulcate concentrically, indicating close ridges or sharp waves of growth upon the outer surface (not visible in our specimens). The inner surface (and probably the outer) shows radiating lines (rather coarse ones) over the median area, but not on the sides.

The pedicle groove is so wide and pyramidal as to open at an angle of 40°; and its edges are so strongly pronounced as to give the appearance of hinge plates. A short median ridge divides this area, and extends but a very short distance. A specimen, apparently of the shorter valve, has also a median line, but fainter and longer. This is uncertain, the specimen being much crushed.

The foregoing description was followed by a description of a variety named *ovalis* by Hicks [Salter and Hicks, 1867, p. 341]. It was collected in the Red Rocks of the Menevian group near St. Davids, and the varietal name was given to it on account of the front edge being "rounded off, and not squared at all." Davidson [1868, p. 307] stated that he did not consider this character of any importance, as he had before him specimens of *L. ferruginea* of a similar size which had the front quite as much rounded off. Davidson [1868, p. 307] also states that there can be no doubt as to the shell termed *Lingulella unguiculus* by Salter in 1865 being the same species as *L. ferruginea* described in 1867. He also states that it is true that *L. ferruginea*, like most of its congeners, varies slightly in its shape in different examples; some having their front and middle more rounded than others, and the posterior portion conyerging rather more in some individuals than in others.

Davidson [1871, p. 336] further observes that—

this small species has been correctly described and illustrated by Mr. Salter; and is, as far as we are aware, the earliest brachiopod hitherto discovered; for specimens [Davidson, 1871, Pl. XLIX, fig. 35] were found by Hicks at the middle and the very base of the purple and red rocks of Sedgwick's "Harlech group," which directly underlies the "Menevian group" or lowest *Lingula* flags. The position is about 1,200 feet (365.8 m.) lower in the series than the specimen described by Salter and Hicks [1867, p. 340]. The shell does not appear to be scarce, but the beds are much cleaved, and their color is not in any way favorable to the exhibition of the characters of so thin a shell.

In my remarks [1884a, p. 15] upon the species "*Lingula? dawsoni*" Matthew, I called attention to the close resemblance between that species and *Lingulella ferruginea*, and said that with only a specimen of the ventral valve for comparison it was difficult satisfactorily to determine the specific relations of the species.

With the large collections now before me from Newfoundland, and Matthew's and our own specimens from New Brunswick, it is possible to refer the form that has been described as *Lingula? dawsoni* to *Lingulella ferruginea*.

Before making comparisons between the American and Welsh representatives of the species described, I will quote the original description of *L. dawsoni* [Walcott, 1884a, p. 15], and add such additional data as the specimens from the other collections of Newfoundland have afforded:

Shell small, broadly subelliptical, subattenuate toward the beak; the margins gradually expanding and curving from the beak to the center, where the shell has its greatest width, and thence narrowing toward the front, which is broadly rounded. General surface depressed, convex, becoming more convex toward the beak.

Surface marked by fine undulating concentric lines crossed by radiating lines that are seen only by the aid of a strong magnifying glass.

In form this species approaches *Lingulella ferruginea* Salter of the Menevian formation of Wales quite closely, but with only a specimen of the ventral(?) valve to compare with it, it is difficult satisfactorily to determine its specific relations.

From the Newfoundland material the following additional description is taken:

The dorsal valve is ovate and moderately convex as it occurs in the shale.

The shell appears to have been thin, and built up of two or more layers or lamellæ. The surface described for the type specimen is correct for the surface when the thin outer layer is exfoliated. The outer surface, as shown by a small bit of it on the type specimen, is of the

same general character as that of *Lingulella radula* Matthew and *Lingulella martinensis* Matthew. It is exceedingly fine and is discernible only with a strong magnifier.

The surface of a specimen represented by Plate LXIX, figure 1t, is marked, in addition to the radiating and concentric lines, by irregular, more or less transverse lines that suggest the surface of species referred to the subgenus *Westonia*. Associated specimens do not show this peculiarity of surface.

The interior of the dorsal valve is not well shown. In two specimens (Pl. XXIX, figs. 1 and 1l) traces of the visceral area are preserved, and the area and pedicle groove are indicated in figure 1f. In the casts of the dorsal valve the area is clearly defined (fig. 1n) and the transmedian (i) and the central muscle scars (h) (fig. 1q). The main trunk of the vascular sinus is far out toward the margins (fig. 1r), and in the same interior the paths of advance of the muscle scars are unusually prominent. A median sinus appears to be indicated in figure 1n.

Observations.—Through the courtesy of Dr. Gilbert D. Harris I have been able to compare the type specimen of "*Lingula? dawsoni*," which belongs to the Hartt collection of Cornell University, with the specimens referred to the species by Matthew. Only one of Matthew's specimens [1886, Pl. V, fig. 9d] belongs to the species. Two other specimens, however, described and figured as "*Lingulella linguloides*" [Matthew, 1886, p. 34], are undoubtedly specifically identical with the original type of "*Lingula? dawsoni*," Matthew's identification being based on the figure of the specimen described and illustrated by me [1884a, p. 15].

Two other specimens illustrated by Matthew [1886, Pl. V, figs. 9, 9a-c] as "*Lingulella dawsoni*" appear to be identical with *L. martinensis* Matthew. Both the ventral and dorsal valves of the two figured specimens are broken away at the beak, and allowance is also made for their being compressed in shale, while the types of *L. martinensis* are embedded in sandstone.

It will be noticed that our Plate XXIX, figure 1, differs from Matthew's figure 9d [1886, Pl. V] in the form of the visceral area, although they are drawn from the same specimen. The shell is small, and the markings are somewhat indistinct, but from what may be seen and from our knowledge of the form of the markings in the closely related species, I think the change in the figure is necessary.

A shell that appears to be identical with this species occurs in the compact, gray, thin-bedded sandstones that are interbedded in the Upper Cambrian shales on McNeil Brook, 1.5 miles (0.94 km.) east of Marion Bridge, Cape Breton, Nova Scotia. The species is abundantly represented, the partings of the shaly sandstone often being nearly covered with the detached valves. The average length of the ventral valve is 3 mm.

Lingulella ferruginea occurs in abundance in the shales and interbedded limestones of the Manuels Brook section, Newfoundland, and also in the dark shales above the Lower Cambrian beds near Topsail Head, on the shore of Conception Bay. In order to exhibit the range of variation caused by the character of the embedding matrix, a number of specimens are illustrated. Plate XXIX, figures 1e to 1k, and 1n, are from the shales; figures 1f, 1i, 1j, and 1k show the effect of compression and distortion, while figures 1l, 1m, 1o, 1p, and 1q, from the limestone, are more convex and regular, although the specimens they represent were chosen as illustrating variation in form.

In the Manuels Brook section, Newfoundland, *Lingulella ferruginea* is associated with *Acrotreta misera*, *Agnostus punctuosus*, *Microdiscus punctatus*, *Paradoxides davidis*, *P. hicksi*, *Anopolenus venustus*, *Conocoryphe elegans*, *Ctenocephalus matthewi*, *Erinnys venulosa*, *Ptychoparia robbi*, *P. variolaris*, *Holocephalina inflata*, *Agraulos socialis*, etc. [Walcott, 1891b, p. 261].

Davidson [1868, p. 306] gives a list of the fossils that occur in association with *Lingulella ferruginea* in the Menevian group of Wales. Among them we find *Paradoxides davidis*, *P. hicksi*, *Erinnys venulosa*, *Ptychoparia variolaris*; also the genera *Holocephalina* and *Anopolenus*.

The above-mentioned association of species in the Newfoundland and Welsh beds shows that *Lingulella ferruginea* occurs in the same relative faunal horizon on the two sides of the Atlantic. A comparison of the illustrations of the type specimens [Salter and Hicks, 1867, figs. 1-3] and those subsequently described and illustrated by Davidson [1871, Pl. XLIX, figs. 33 and 35] shows clearly that there are no true specific differences between the two species.

In order to place these clearly before students, the original figures of Salter [Salter and Hicks, 1867, figs. 1-3] and Davidson [1871, Pl. XLIX, figs. 33 and 35] are reproduced on Plate XXIX.

"*Leptobolus gemmulus*" Matthew [1903, p. 190] appears to be a true *Lingulella* and specifically identical with *L. ferruginea*. It occurs at a higher horizon (Division 3c of Matthew's section) than the typical forms of the latter in Wales and near St. John, New Brunswick, but that is not surprising for a species which has so wide a geographic distribution. Only one specimen from the type locality at Navy Island, St. John, sent to me by Matthew, shows the area and central groove of the ventral valve. In the shales of his Division C3e on McLeod Brook, Cape Breton, Matthew collected a fine series of compressed and flattened shells that he referred to "*Leptobolus gemmulus*." These shells appear to have the broad form as the result of being flattened in the shale. The same changes occur in typical specimens of *L. ferruginea* when flattened in the shales at Andrarum, Sweden. In the interbedded limestones they are narrower and more convex. I note the same differences also in specimens from the shaly sandstones of McNeil Brook, Cape Breton. The narrow, uncompressed forms are shown by Plate XXXV, figures 4, 4a-b. In the same sandy shales occur flattened shells that are as broad as those referred to "*Leptobolus gemmulus*" Matthew [1903, p. 190] (Pl. XXIX, figs. 1u and 1v).

Lingulella lepis Salter, when uncompressed, has the broad form given to *L. ferruginea* by compression, and would be compared with Matthew's "*Leptobolus gemmulus*" if the latter were retained as a species.

A species that appears to be identical with this occurs at Hastings Cove, St. John County, New Brunswick, and a closely allied form, compared by Matthew [1895a, p. 115] with *Lingulella granvillensis*, occurs in the "*Protolenus* beds" of Hanford Brook, St. John County, New Brunswick.

Linnarsson [1876, Pl. III] gives several illustrations of a small *Lingulella* from the *Paradoxides* beds. One of them (see Pl. XXXI, fig. 3c) is an elongate form that may represent a distinct species from the broader forms represented by Plate XXXI, figures 3, 3a, and 3b in this monograph. A direct comparison between specimens from the limestones of Sweden and Newfoundland leads to the conclusion that they belong to the same species.

Kayser [1897, Pl. VII, fig. 7] illustrates a species of *Lingulella* from Iruya, northern Argentina, that he compares with *L. ferruginea* Salter. It certainly resembles that species very closely, and with our present knowledge of the wide distribution of *L. ferruginea*, I believe we are justified in identifying the South American form as the representative of that species. The figure given by Kayser [1897, Pl. VII, fig. 7] is reproduced on Plate XXX. The associated species given by Kayser [1897, pp. 277-281] are *Liostracus ulrichi*, *L. steinmanni*, *L. sp.*, *Agnostus iruyensis*, *Lingulella cf. davisii*, and *Orthis saltensis*.

FORMATION AND LOCALITY.^a—Upper Cambrian: (3h) Shale and shaly limestone on McNeil Brook, 1.5 miles (2.4 km.) east of Marion Bridge; (307 [Matthew, 1903, p. 192]) shales of Division C3c of Matthew, on McLeod Brook (=Barachois River); and (307a [Matthew, 1903, p. 240]) shales of Division C3c2 of Matthew, on McLeod Brook (=Barachois River), near Boisdale; all in eastern Cape Breton, Nova Scotia, Canada.

(308 [Matthew, 1892, p. 41]) Shales of Division C3c of Matthew at Navy Island, St. John Harbor, St. John County, New Brunswick, Canada.

(3) Shaly limestones 300 feet (91.4 m.) above the *Paradoxides* zone, Manuels Brook, Conception Bay, Newfoundland.

(310d) *Ceratopyge* slate at Borgholm, Oeland Island, Sweden.

(389d [Kayser, 1897, p. 280]) Iruya, Province of Salta, Argentina, South America.

Middle Cambrian: (3i) Compact, fine-grained, thin-bedded, gray sandstone of the *Paradoxides* zone, on McLean Brook, 1 mile (1.6 km.) east of McCodrum Brook, and 1.5 miles (2.4 km.) west of Marion Bridge, eastern Cape Breton, Nova Scotia, Canada.

(2s) Limestone in upper part of *Paradoxides* zone, at Hastings Cove [Matthew, 1898b, p. 38], on Kennebecasis Bay, 0.5 mile (0.8 km.) northeast of Torryburn, on the Intercolonial Railway northeast of St. John; (2i) sandstones of Division 1b3 of Matthew's [1895a, p. 108] *Protolenus* zone, on Hanford Brook; and (21) limestone at the base of the *Paradoxides* zone [Matthew, 1895a, p. 108]; all on Hanford Brook, St. John County, New Brunswick.

(3011) Shales of Division 1d of Matthew on Porters Brook, St. Martins; (2m) shales near the base of the *Paradoxides* zone on Hanford Brook; (301k) St. John formation in the city of St. John; (301h) shales of Division 1c of Matthew, on Hanford Brook; (301g) sandstones of Division 1c of Matthew, at Portland (now a part of the city of St. John); and

^aThis species also occurs at Localities 318u and 318v, p. 249.

(301z) in Division 1c of Matthew at Ratcliffs Millstream; all [Matthew, 1886, p. 34] in St. John County, New Brunswick.

(1a, 61, and 6n) Shales near the top of No. 6 of the Manuels Brook section; (6r and 6u) limestone and shale, respectively, on the west side of Manuels Brook; (1) shales of zone A of No. 7 of the Manuels Brook section; and (2) shales of zone B of No. 7 of the Manuels Brook section; all on Manuels Brook [Walcott, 1891b, p. 261], Conception Bay, Newfoundland.

(2a) Shales from same horizon as No. 1, Topsail Head, Conception Bay, Newfoundland.

(6g) Limestone near the base of the Middle Cambrian, the lowest horizon carrying *Paradoxides*, northwest side of Chapple Arm Harbor, about 1 mile (1.6 km.) from its head, Trinity Bay, Newfoundland.

(318j) [Salter, 1866b, p. 340] Black shales of the Menevian group at Pen-y-pleidiaw, St. Davids; (318h) shales in the Menevian at St. Davids; (318o)^a red shales at the base of the Harlech grits at Solva; (366b) red shales at the base of the Harlech grits at Porthelais Harbor, south of St. Davids; and (318n)^a red shales at the base of the Harlech grits at St. Davids; all in South Wales.

(318e)^a Lower portion of the Menevian at Camlan; (318k)^a in the Menevian rocks at Tafern Helig; (3181)^a in the Menevian rocks at the Waterfall Valley, near Maentwrog; all in North Wales.

(8w) Limestones of the *Paradoxides forchhammeri* zone, at Andrarum, 20 miles (32.2 km.) northwest of Simrishamn, Province of Christianstad; (310q) limestone of the *Agnostus lævigatus* zone at Lovened, Province of Skaraborg; (320m [Linnarsson, 1876, p. 15]) limestones of the *Paradoxides forchhammeri* zone at Kinnekulle, Province of Skaraborg; (320n [Linnarsson, 1876, p. 16]) limestones of the *Paradoxides forchhammeri* zone at Lovened, Djupadal, 19 miles (30.6 km.) south-southeast of Skara, Province of Skaraborg; (310m [Linnarsson, 1876, p. 16]) arenaceous shales of the *Paradoxides tessini* zone on Oeland Island; (310o) limestone of the *Paradoxides tessini* zone at Borgholm, Oeland Island; (310p) limestone of the *Paradoxides olandicus* zone at Borgholm, Oeland Island; (310y) limestone at Kiviks Esperöd, Province of Malmöhus; and (310z) limestone at Brantevik, on the shore a little south of Simrishamn, Province of Christianstad; all in Sweden.

(16h) Limestones of the *Paradoxides forchhammeri* zone at Borregaard; and (16j) limestones of the *Paradoxides forchhammeri* zone at Laeså; both on Bornholm Island, Denmark.

(324d) Windjuelandet, Ringsaker, Province of Hedemarken, Norway.

This species is somewhat doubtfully identified from the following localities:

Upper Cambrian: (6s) Just north of Fosters Point, Random Island, Random Sound, Newfoundland.

Middle Cambrian: (1) Shales of zone A of No. 7 of the Manuels Brook section [Walcott, 1891b, p. 261], Manuels Brook, a small stream which flows into Conception Bay from the east, near Topsail Head, Newfoundland.

(2i) Sandstones of Division 1b3 of Matthew's [1895a, p. 108] *Protolenus* zone, Hanford Brook, St. John County, New Brunswick.

LINGULELLA cf. FERRUGINEA.

Plate XXX, figure 4.

Lingulella (?) sp. POMPECKJ, 1896, Jahrb. K.-k. geol. Reichsanstalt, Bd. 45, Hft. 3, p. 509, Pl. XIV, figs. 16a-b.

(Described in German; see below for translation. Figs. 16a-b are reproduced in this monograph, Pl. XXX, fig. 4.)

The original description by Pompeckj is as follows:

There is on hand a ventral valve which, owing to its bad state of preservation, can not be assigned to the genus *Lingulella* otherwise than doubtfully.

Outline elongated, pentagonal with corners rounded off. The length is somewhat more than double the breadth. The vertex (beak?) is drawn far forward. The surface shows a concentric striation. In front of the vertex (beak?) is seen a short median groove.

The form recalls *Lingulella* (?) sp. undt., which Linnarsson [1876, p. 15] described from Kinnekulle; but it is more slender than the species made known from the *Paradoxides* slate of Sweden.

This little shell is probably the representative of *Lingulella ferruginea* Salter of the English and Swedish *Paradoxides* fauna.

FORMATION AND LOCALITY.—**Middle Cambrian:** (345 [Pompeckj, 1896b, p. 509]) Greenish shales in the *Paradoxides* zone on the Dlonhá Hora, above the brook of Sbirov, near Skrej, Bohemia, Austria-Hungary.

LINGULELLA FLUMENIS (Matthew).

Plate XXXV, figures 6, 6a-b.

Leptobolus flumenis MATTHEW, 1903, Geol. Survey Canada, Rept. Cambrian Rocks Cape Breton, pp. 189-190, Pl.

XI, figs. 7a-f. (Described and discussed as a new species; see p. 501 for copy. The specimens represented by figs. 7a, 7b, and 7e are redrawn in this monograph, Pl. XXXV, figs. 6, 6a-b, respectively.)

^a Davidson, 1871, p. 337.

The original description by Matthew is as follows:

A narrowly ovate species, somewhat straight on the sides, and broadly rounded in front.

The ventral valve has an obtusely pointed beak, bent down at the apex. Sides of the valve somewhat sharply sloped in the posterior half and gently sloped in front. *Interior*.—This shows an area nearly half a millimeter long, and a visceral callus extending about half the length of the valve. The lateral ridges within the valve extend as far; and in front of them, reaching to within a sixth of the length of the valve from the front, is a pair of arched vascular grooves not far from the margin of the valve; numerous external branches from these trunk grooves extend to the flattened margin of the valve. The individual length of these branches is about equal to the width of the main groove.

The dorsal valve is obtusely rounded at the hinge area, which is very short, and here and at the sides the valve is strongly arched downward, but is gently sloped down in front. *Interior*.—In front of the linear cardinal area is a pair of pits marking the insertion of the cardinal muscles. The middle of the valve for more than half the valve's length has a flattened band marking the progress of the central muscles during the growth of the shell. At the front this band is about one-sixth or one-eighth of the width of the valve, and at its sides are faint prints of the central muscles; and at the front are two pairs of minute pits, one or both of which marks the position of the anterior laterals. The place of the posterior laterals is marked by a series of small pits near the margins in the posterior third of the valve. In front of these pits are the strong arched grooves left by the vascular trunks, which extend across the middle half of the valve near its margins.

No examples have been obtained showing the surface markings, except those near the front of the valve; but both valves show from four to six ridges of growth in the anterior quarter of the valve. These ridges are broadly curved in the middle part, but more abruptly at the sides.

Ventral valve 4 mm. long and 2.5 mm. wide. The dorsal valve is nearly one-half millimeter shorter than the ventral.

This species is of nearly the same size as *L. insulæ*, but is less elliptical in outline, and the valves are more flattened in front; the area of the ventral valve also is longer, and that of the dorsal shorter than in that species; also the central group of muscles is not set so far forward as in that of the dorsal of the species cited.

This species differs from *L. atavus* of the Etcheminian terrane in having the central muscles of both valves set farther back.

The exact horizon of this species is uncertain, as the outcrop is in an isolated basin [Matthew, 1903, p. 51]. Matthew correlated it with his section on the lithologic character of the matrix. The form is very much like that of *Lingulella collicia* (Matthew), and it appears to be identical with small shells of the latter species.

FORMATION AND LOCALITY.—**Middle Cambrian:** (325a [Matthew, 1903, p. 190]) Shales of Division C2c of Matthew's [1903, p. 49] Bretonian on the eastern slope of the valley of McNeil Brook, on the road to Trout Brook, in the Mira River valley, eastern Cape Breton, Nova Scotia.

LINGULELLA FRANKLINENSIS (Walcott).

Plate XXVI, figures 3, 3a-b.

Obolus (Lingulella) franklinensis WALCOTT, 1898, Proc. U. S. Nat. Mus., vol. 21, pp. 404-405. (Described and discussed essentially as below as a new species.)

Shell small, ovate, moderately convex, with the apex of the dorsal valve subacuminate. Surface of the shell marked by rather strong lines and striæ of growth, with very fine, slightly irregular, wavy striæ between the coarser concentric striæ. Two ventral valves referred to this species have a length of 3 and 3.5 mm., respectively, with a width of about 2.75 mm. There are no dorsal valves in the collection. A partial cast of the interior of the shell carries an impression of radiating striæ, a strong cast of a narrow pedicle furrow, and a few concentric lines of growth. If the shell represented by Plate XXVI, figure 3b, belongs to this species, the interior surface was also marked by scattered bits of punctæ.

Observations.—This species is founded on three specimens of the ventral valve that occur in the limestones interbedded in dark shales above the Lower Cambrian *Olenellus*-bearing shales. A larger shell (Pl. XXVI, fig. 3b) has the same surface characters and occurs at the same relative geological horizon, and it may belong to this species; the only specimen of it in the collection is apparently a dorsal valve. The exact stratigraphic horizon has not been determined, but from the associated species of *Agnostus* and *Ptychoparia* it appears that the reference should be to the Middle Cambrian.

The material for study is so limited that it is difficult to make comparisons with other species. In form the ventral valve resembles that of *Lingulella lineolata* (Walcott) (Pl. XLVIII), *L. tarpa* (Walcott) (Pl. XXIII), and in some respects *L. granvillensis* Walcott (Pl. XXII), with which it would be more naturally compared owing to its belonging to the Appalachian fauna.

The specific name is derived from Franklin County, Vermont, in which the species occurs.

FORMATION AND LOCALITY.—Middle Cambrian: (28a) "St. Albans formation," in limestone lentil about 1 mile (1.6 km.) east of Parker's quarry, west of Georgia; (319v) sandy shale, 2 miles (3.2 km.) east of Highgate Springs; and (87) conglomerate limestone 1 mile (1.6 km.) south-southwest of Highgate Falls; all in Franklin County, Vermont.

LINGULELLA FUCHSI Redlich.

Plate XXXIX, figures 2, 2a-c, 3.

Lingulella fuchsi REDLICH, 1899, Mem. Geol. Survey India, Paleontologia Indica, new ser., vol. 1, No. 1, Cambrian Fauna of the Eastern Salt Range, p. 7, Pl. I, figs. 10a-e. (Described and discussed as a new species. Fig. 10c is reproduced in this monograph, Pl. XXXIX, fig. 3.)

Obolus (Lingulella) fuchsi (Redlich), WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 332. (Discussed somewhat as below.)

In the collection of fossils received from Doctor Noetling I find, associated with *Lingulella wanniecki* Redlich, a small elongate form that appears to be identical with *L. fuchsi* of Redlich. Redlich states [1899, p. 10] that his *L. fuchsi* occurs in a hard clay above the lower magnesian sandstones which rest on the shales containing *L. wanniecki*. If my identification of the species is correct, *L. wanniecki* has a greater vertical range, or there may have been some error in the identification and labeling of the zone from which the original specimens were obtained. The identification of the species in the material before me is based on the form of the ventral valve, as shown by Redlich's figure 10c [1899, Pl. I] and my figure 2 (Pl. XXXIX). The dorsal valves represented by Plate XXXIX, figures 2a-c, differ materially from Redlich's illustration; but in the specimen represented by figure 2d the little pit mentioned by Redlich [1899, p. 7] is shown, also two ridges that leave a concave furrow in the central portion of the cast of the valve. These are the lines of the main vascular sinuses.

FORMATION AND LOCALITY.—Middle Cambrian: (15r)^a Dark argillaceous shale, at Khussak, Salt Range, India.

LINGULELLA GRANDIS (Matthew).

Plate XXXVIII, figures 2, 2a-f.

Leptobolus grandis MATTHEW, 1894, Trans. Roy. Soc. Canada for 1894, 1st ser., vol. 11, sec. 4, No. 8, pp. 91-92, Pl. XVI, figs. 7a-c. (Described and discussed as a new species. The specimens represented by figs. 7a and 7b are redrawn in this monograph, Pl. XXXVIII, figs. 2b and 2f, respectively.)

Lingulella? cuneata MATTHEW, 1894, idem, pp. 92-93, Pl. XVI, figs. 5a-b. (Described and discussed as a new species. Matthew's types of *Lingulella cuneata* are figured in this monograph, Pl. XXXVIII, figs. 2, 2a, 2c, and 2d, but it is impossible to tell which of these Matthew figured, Pl. XVI, figs. 5a-b.)

Lingula cf. *billingsiana* WHITEAVES, MATTHEW, 1894, idem, p. 93, Pl. XVI, figs. 6a-b. (Described and discussed.)

Lingulella? billingsiana SCHUCHERT (in part) [not (WHITEAVES)], 1897, Bull. U. S. Geol. Survey No. 87, p. 256. (Merely changes generic reference of Matthew's species *Lingula* cf. *billingsiana* cited above.)

Not *Leptobolus* cf. *grandis* MATTHEW, 1902, Trans. Roy. Soc. Canada for 1902, 2d ser., vol. 8, sec. 4, No. 3, p. 111. (Characterized. This species is given by Matthew as occurring on Mount Stephen, British Columbia. For the species occurring at this locality see pp. 127-128.)

General form subcuneate, with the ventral valve acuminate and the dorsal valve elongate-ovate; valves more than usually convex for a species of the genus. Surface of shell marked by concentric striae and strong lines of growth, and, where the outer surface is perfect, by almost microscopic, irregular, semi-inoesulating, elevated striae, that under a high power give the surface an appearance somewhat similar to that of *Lingulella (Lingulepis) roberti* (Matthew) and *Obolus (Westonia) ella* (Hall and Whitfield) (Pl. XLVII). In almost every instance this surface adheres to the matrix, leaving the glossy inner surface described by Matthew [1894, p. 92]; the inner layers or lamellae are marked by numerous fine radiating striae and concentric growth lines;

^aSpecimens from the type locality were given to the United States National Museum and this number was assigned to them.

a few large punctæ were seen on the interior of one ventral valve. The shell is unusually thick for its size. It has a thin outer layer and several inner layers or lamellæ that are arranged very much as in *Lingulella acutangula* (Roemer) (Pl. XVII).

A relatively large ventral valve has a length of 7 mm. and a width of about 5.5 mm.

The cast of the area of the ventral valve shows a long area divided midway by a narrow pedicle groove, and toward the lateral margins by a very narrow flexure line. The area of the dorsal valve is shorter in proportion than that of the ventral valve, and also less extended on the cardinal slopes. The cast of the visceral cavity (v), including the outline of the heart-shaped cavity (x), is very well shown by Plate XXXVIII, figures 2a and 2b. There are no traces of a median septum in the ventral valve, but in the dorsal valve it is a very narrow sharp crest on the summit of the broad, strong, median ridge that extends from the area fully three-fourths of the distance to the front margin; the septum appears to be confined to the anterior half of the length of the ridge.

The muscle scars are not clearly defined in either valve. The trapezoidal areas of the ventral valve, where the central scars and the middle and outside laterals are usually located, are present, but the individual scars can not be differentiated. In the dorsal valve the central scars appear to be unusually large; they are situated on each side of the broad median ridge, and crowd the parietal scar out to the main vascular sinus; the anterior laterals are situated on each side of the median septum, as shown in Plate XXXVIII, figure 2d, but they are not well defined.

The main vascular sinuses of the ventral valve extend far forward and curve inward so that they appear nearly to unite a short distance back of the anterior margin of the shell; their interior lateral branches appear to touch, and thus give the appearance of uniting the two main sinuses; the lateral branches extend outward from the main sinus nearly to the edge of the shell, while the interior lateral branches are crowded into the space between the main vascular sinuses and the visceral area. The main vascular sinuses of the dorsal valve extend well forward and curve inward toward the median line; their interior lateral branches fill the narrow space between the vascular cavity and the main sinuses; no traces have been observed of the peripheral branches of the vascular system of the dorsal valve. The parietal scar is shown more clearly for the dorsal than for the ventral valve. In the former it extends about the space occupied by the central scars, but it has not been traced outside of the main sinuses or in front of the anterior lateral muscle scars.

Observations.—I was greatly puzzled when studying Matthew's figures [1894, Pl. XVI] of "*Leptobolus grandis*, *Lingulella? cuneata*, and *Lingula* cf. *billingsiana*." It seemed, after extended study of the character and variation of the interior markings of *Obolus* and *Lingulella*, that the three species should be referred to *Lingulella* and perhaps to one species. Doctor Matthew very kindly sent me his material, including the type specimens of this species. At first I was inclined to consider "*Leptobolus grandis*" as distinct from *Lingulella*, but on close study it became more and more evident that the differences were such that a generic distinction could not be based upon them. The anterior extension of the main vascular sinuses varies both in form and degree with different species of *Lingulella*. This may be seen by comparing *Lingulella ampla* (Owen), *Lingulella acutangula* (Roemer), etc. The position and size of the visceral area and muscle scars of the dorsal valve are also subject to great variation, as may be seen by comparing *Lingulella acutangula*, and *L. ampla*.

All of the material of Matthew's "*Leptobolus grandis*, *Lingulella? cuneata*, and *Lingula* cf. *billingsiana*" is from one locality and bed. It comprises a large number of shells on some twenty-seven pieces of rock. I found that there was more or less distortion of the shells by both vertical and lateral compression. Where the interior markings are well preserved the shells can be at once referred to *Lingulella grandis*. It is only in shells that are distorted or a little larger, or where the interior is imperfectly shown, that any doubt arises, and even in this case no undoubted dorsal valve was found that could be referred to any other species than *L. grandis*.

The illustrations of "*Lingulella? cuneata*" [figs. 5a and 5b] and "*Lingula* cf. *billingsiana*" [figs. 6a and 6b] by Matthew [1894, Pl. XVI] are all of ventral valves, and the figures of "*Leptobolus*

grandis" [figs. 7a and 7b] are so diagrammatic that it is impossible to make comparisons between them and the drawings of the same specimens which accompany this monograph.

FORMATION AND LOCALITY.—Lower Ordovician: (301s) Gray sandstones of Division 3e(?) of Matthew [1894, p. 91] at McAphee's corner, Hardingville, St. John County, New Brunswick.

LINGULELLA GRANVILLENSIS Walcott.

Plate XXII, figures 1, 1a-d.

Lingulella granvillensis WALCOTT, 1887, Am. Jour. Sci., 3d ser., vol. 34, pp. 188-189, Pl. I, figs. 15, 15a-c. (Described and discussed as a new species. The specimens represented by figs. 15, 15a, and 15b are redrawn in this monograph, Pl. XXII, figs. 1c, 1d, and 1, respectively.)

Lingulella granvillensis Walcott, OEHLERT, 1889, Annuaire géologique universel for 1888, tome 5, p. 1138. (Described in French in a review of the preceding reference.)

Lingulella granvillensis WALCOTT, 1891, Tenth Ann. Rept. U. S. Geol. Survey, pp. 607-608, Pl. LXVII, figs. 4, 4a-d. (Description and figs. 4, 4a-c, copied from Walcott, 1887, p. 188, Pl. I, figs. 15, 15a-c.)

Lingulella granvillensis Walcott, HALL and CLARKE, 1892, Nat. Hist. New York, Paleontology, vol. 8, pt. 1, p. 58. (Discussed.)

General form rather broadly ovate, with the ventral valve obtusely acuminate and the dorsal valve obtusely oval. Valves moderately convex, the dorsal being somewhat more so than the ventral. Surface of shell marked by concentric lines of growth, with very fine, slightly undulating striæ between them, and a few very indistinct radiating striæ. The character of the surface of the inner layers and of the interior of the shell is unknown. The shell appears to have been rather thin and formed of a thin outer layer and one or more inner layers or lamellæ.

A rather large ventral valve has a length of 6 mm. and a width of 4.5 mm., and an associated dorsal valve 5 mm. in length has a width of 3.5 mm. The interior of a small ventral valve shows the visceral area and the two main vascular sinuses; on a cast of the dorsal valve the main vascular sinuses are shown, also a fine irregular network of interior branches of the main sinuses and a few peripheral branches of the vascular system. These are shown by Plate XXII, figure 1d. A broad, low ridge, represented on the cast by a shallow depression, extends forward in front of the area two-thirds the distance toward the frontal margin. It is marked on the median line near the center of the shell by a sharp, narrow median septum, and lines indicating the path of advance of the central and anterior lateral muscle scars. The scars are not clearly defined, but appear to be situated as indicated on figure 1d. In front of the anterior lateral muscle scars there is a peculiar rhomboidal area that is not so well defined in any other species.

Observations.—This is one of the small species that in size and general form resembles *Lingulella ferruginea* Salter of the Middle Cambrian of the Atlantic basin; also *L. manticula* (White) of the Upper Cambrian and Lower Ordovician of the Rocky Mountain region; it differs from the former in its broader anterior outline and from the latter in its more acuminate form and shorter area.

This form owes its specific name to the occurrence of the type specimen near Granville, New York.

FORMATION AND LOCALITY.—Lower Cambrian: (20a) Gray limestone, interbedded with shaly slates, in a lane west of Lafayette Stevens's house, about 100 yards (91.4 m.) from the main road, in the southern part of Whitehall Township, Fort Ann quadrangle (U. S. Geol. Survey); (21a) limestone below the first fall of Mettawee River, above the North Granville bridge, Fort Ann quadrangle (U. S. Geol. Survey); (37b) limestones 0.25 mile (0.4 km.) east of Salem, Cambridge quadrangle (U. S. Geol. Survey); (38a) limestone 2 miles (3.2 km.) south of North Granville, on the first road which turns south from the road running between that village and Truthville, 4 miles (6.4 km.) west-northwest of Granville, Fort Ann quadrangle (U. S. Geol. Survey); (34) limestone on roadside a little west of the bridge over Poultney River, at Low Hampton, about 5 miles (8 km.) east-northeast of Whitehall, Whitehall quadrangle (U. S. Geol. Survey); (338m) limestone on the roadside north of schoolhouse No. 4, in the northeast part of Whitehall, Whitehall quadrangle (U. S. Geol. Survey); (35) limestone 1.5 miles (2.4 km.) north of Bald Mountain, and 3.5 miles (5.6 km.) north-northwest of Greenwich, Schuylerville quadrangle (U. S. Geol. Survey); (38) limestone 0.25 mile (0.4 km.) north of John Hulett's farmhouse about 3 miles (4.8 km.) west of South Granville, and 4.5 miles (7.2 km.) southwest of Granville, Fort Ann quadrangle (U. S. Geol. Survey); and (338l) limestone in

the northern part of Easton Station, 3 miles (4.8 km.) south of Greenwich, Cambridge quadrangle (U. S. Geol. Survey); all in Washington County, New York.

(29) Limestone just above the bridge at the Stockport paper mill, on Kinderhook Creek; and (44b) limestone near North Chatham in the northern part of the Kinderhook quadrangle (U. S. Geol. Survey): both in Columbia County, New York.

(25a) Limestone on the Hall (Donaldson's) farm, 2 miles (3.2 km.) east of Swanton, Franklin County, Vermont.

LINGULELLA HAYESI (Walcott).

Plate XXV, figures 1, 1a-j.

Obolus (Lingulella) hayesi WALCOTT, 1898, Proc. U. S. Nat. Mus., vol. 21, pp. 405-406. (Described and discussed as a new species, essentially as below.)

Shell small; general form broad ovate, with the ventral valve obtusely acuminate and the dorsal valve rounded ovate; valves moderately convex. Outer surface as seen in casts marked by fine, concentric lines and striæ of growth; the inner surface had fine, radiating striæ and scattered pits or punctæ. The shell appears from the casts to have been of medium thickness and built up of several layers or lamellæ.

The average length of the ventral valve is about 3.5 mm.; width about 3 mm. The dorsal valves are a little shorter than the ventral valves, the length and width being about the same, although some of the shells are a little wider than long.

The casts of the interior of the ventral valve show a clearly defined, strong area, divided midway by the cast of a narrow pedicle groove, and again by sharp flexure lines situated a little nearer the pedicle groove than to the lateral margins. The striæ of growth cross the area parallel with its base, arching over the cast of the pedicle furrow. The area formed a thin shelf between the pedicle groove and the lateral margins, the undercut extending back under the area as shown in the cast by a thin projection of the embedding rock over the area. The area of the dorsal valve is of medium length and marked by striæ of growth and rather clearly defined flexure lines.

The cast of a ventral valve shows the visceral cavity and rather strong and long main vascular sinuses. In the dorsal valve the main vascular sinuses are frequently outlined very beautifully on the siliceous casts; the visceral area surrounded by the parietal band is clearly defined, also the central and anterior lateral muscle scars, and in one cast the transmedian muscle scars.

Observations.—This very pretty species occurs quite abundantly on the siliceous nodules embedded in the Conasauga ("Coosa") shale. It resembles in form *Obolus lamborni* (Meek) and *Obolus willisi* (Walcott), but is a much smaller species. The elongate visceral cavity of the dorsal valve is also of the same type as that of those species. The thickening in front of the visceral cavity (Pl. XXV, fig. 1b) is similar to that which occurs in *Obolus matinalis* (Hall) (Pl. V, fig. 1d). In this character and in its broadly ovate form it comes very close to the forms which are referred to *Obolus*.

The specific name was given in honor of Dr. C. W. Hayes, at that time chief geologist of the United States Geological Survey.

FORMATION AND LOCALITY.—Middle Cambrian: (90x and 94a)^a In and attached to the outer surface of siliceous nodules in the Conasauga ("Coosa") shale, Coosa Valley, east of Center, Cherokee County, Alabama.

LINGULELLA HEBERTI Barrois.

Plate XXXIX, figures 11, 11a-c.

Lingulella heberti BARROIS, 1882, Mém. Soc. géol. du Nord, vol. 2, pp. 185-186, Pl. IV, figs. 3a-d. (Described and discussed in French as a new species; see below for translation. Figs. 3a-d are reproduced in this monograph, Pl. XXXIX, figs. 11, 11a-c, respectively.)

The original description by Barrois follows:

Shell corneous, regular, elongated, slightly convex, scarcely inequivalve. Enlarged in the pallial region where the outline is rounded; pointed at the beaks; longer than wide. Marked with well-developed concentric lines of

^a 90x is the type locality.

growth, some of which are stronger than others. The shell is covered with small fine tubercles, in lines, like certain species of *Kingena* from the Cretaceous, and produced by the fine, oblique, granular striae. (Pl. XXXIX, fig. 11c.)^a

The internal molds (Pl. XXXIX, fig. 11b)^a show clearly that the beaks were provided with a strong pedicle furrow much like that of *Lingulella davisi*, to which these shells have considerable resemblance. The median septum is well marked, likewise the depressions corresponding to the point of attachment of the muscles of the pedicle (Pl. XXXIX, fig. 11b),^a and also the transmedian muscles.

Observations: The *Lingulella heberti* is clearly related to *Lingula attenuata* Sowerby from the Llandeilo flags. It is distinguished by the ornamentation of the shell, which recalls that of *Lingulella granulata* (Phillips). It should also be compared with the form figured by Linnarsson [1876, Pl. III, figs. 24–30] under the name of *Lingulella? nathorsti*, from the *Paradoxides forchhammeri* beds of Sweden. The latter is perhaps a little longer, but has a very great resemblance to our shell. Mr. Davidson, who has kindly communicated to me the results of his examination of this small shell, so abundant at the base of the Silurian sandstones of Cape Vidio, agrees with us in referring it to the genus *Lingulella*; he believes that despite its resemblance to *Lingulella davisi* and *L. granulata*, it would probably rank as a new species. It is dedicated to M. Hebert, to whom we owe so many discoveries in Pyrenean geology.

Dimensions: Length, 8 to 10 mm.; breadth, 7 to 9 mm.

FORMATION AND LOCALITY.—Ordovician: (350a) Sandstones of the stage of Cabo Busto, in the cliffs of Cape Vidio, Province of Oviedo; and (350b) sandstones of the stage of Cabo Busto, at Los Negros; both [Barrois, 1882, p. 186] in northeastern Spain.

LINGULELLA HELENA (Walcott).

Plate XXIV, figures 3, 3a–d.

Obolus (Lingulella) helena WALCOTT, 1898, Proc. U. S. Nat. Mus., vol. 21, p. 406. (Described and discussed essentially as below as a new species.)

General form ovate, with the ventral valve obtusely acuminate, and the dorsal valve rounded ovate. Valves moderately convex, as far as can be determined from their condition of preservation in the shales. Surface of shell marked by rather strong lines of growth, and very fine irregular, radiating, concentric striae that appear to inosculate, the surface having something of the appearance of *Obolus (Westonia) ella* (Hall and Whitfield). The character of the surface markings of the inner layers and the interior of the shell is unknown. So far as can be determined the shell is rather thin, and formed of a thin outer layer and one or more thin inner layers or lamellae. A ventral valve 8 mm. in length has a width of 6 mm.; another 7.5 mm. in length has a width of 6 mm. An associated dorsal valve 7 mm. in length has a width of 5 mm. These variations in outline are to a considerable extent due to distortion.

As shown in the cast of the interior of the shell, the area of the ventral valve is rather long, and marked midway by a strongly defined cast of a pedicle groove, and midway between that and the outer margin by a very distinct flexure line. The area of the dorsal valve is rather long and quite distinctly marked on a cast of the interior. The cast of the interior of the ventral valve shows a strong main vascular sinus (vs) on each side of the visceral area, and in a cast of the dorsal valve a slight median septum is indicated, also traces of the main vascular sinuses. The only traces of the muscle scars observed are the anterior laterals (j) and a suggestion of the central scars in the dorsal valve.

Observations.—This species is associated with *Obolus (Westonia) ella* (Hall and Whitfield) in the siliceous shales near Helena, Montana, and what may be a similar form (Pl. XXIV, fig. 3d) occurs with the same species in Big Cottonwood Canyon, Utah, although the latter is quite closely related to *Obolus mcconnelli* (Walcott). In form and surface characters it belongs to the group of which *Obolus (Westonia) ella* may be taken as a type. It differs from *O. (W.) ella* in being narrower anteriorly and in its more acute beak.

The specific name is derived from Helena, Montana, near which the type specimen was collected.

FORMATION AND LOCALITY.—Middle Cambrian: (30a) Shale on the north side of Big Cottonwood Canyon, 1 mile (1.6 km.) below Argenta, Wasatch Range, southeast of Salt Lake City, Salt Lake County, Utah.

(54s) Dark blue-gray Langston limestone [Walcott, 1908f, p. 198], just above the Cambrian quartzitic sandstones, north side of Twomile Canyon, near its mouth, 2 miles (3.2 km.) southeast of Malade, Oneida County, Idaho.

(4n) Limestone about 325 feet (99.1 m.) above the unconformable base of the Cambrian in divide at the head of Jackson Creek (locally known as Sheep Creek), a creek flowing into Jackson Lake about 0.5 mile (0.8 km.) south of its northwestern corner, Teton Mountains, Grand Teton quadrangle (U. S. Geol. Survey), Uinta County, Wyoming.

^a Barrois's figures are copied in this monograph, and these references are to the figures which correspond with those mentioned by him.

(302s) *Dark siliceo. s shale in a quarry in Last Chance Gulch, south slope of Mount Helena, 1.5 miles (2.4 km.) south of Helena;* and (4a) shales in the Gallatin formation of Peale [1893, Pl. IV], northwest side of canyon, 0.5 mile (0.8 km.) south of Helena; both in Lewis and Clark County, Montana.

LINGULELLA ? HUMILLIMA (Barrande

Plate XXX, figure 12.

Lingula humillima BARRANDE, 1868, Faune silurienne des environs de Hof, en Bavière, p. 101, fig. 70. (Characterized in French as a new species. Fig. 70 is reproduced in this monograph, Pl. XXX, fig. 12.)

Lingula humillima BARRANDE, 1868, Neues Jahrb. für Mineralogie for 1868, p. 691, unnumbered plate, fig. 70. (Copy of preceding reference.)

This species was described from a single small, oval, compressed shell. The author states that its appearance does not permit its identification with any other described species. The shell has a length of 5 mm.; width, 3.5 mm.

FORMATION AND LOCALITY.—**Passage beds** between the Upper Cambrian and the Ordovician: (303c [Barrande, 1868a, p. 101]) *Suburbs of Hof*; and (303f [Pompeckj, 1896a, pp. 7 and 8]) railway cut near Schellenberg, a little distance back of the railway station at NeuhoF, near Hof; both in Bavaria, Germany.

LINGULELLA INO (Walcott).

Plate XXVI, figures 4, 4a-b.

Obolus (Lingulella) ino WALCOTT, 1898, Proc. U. S. Nat. Mus., vol. 21, pp. 406-407. (Described and discussed essentially as below as a new species.)

Shell a little smaller than the average of the species of the genus. General form ovate, with the ventral valve subacuminate and the dorsal valve ovate in outline. There is some range of variation in the outline of the valves, but as a whole they do not vary more than the difference shown in the ventral valve by Plate XXVI, figures 4, 4a. The convexity of the valves is fairly strong, as the shells are preserved in the somewhat shaly sandstones. Ventral valves 7 mm. in length have a width of from 5.5 to 6 mm.; a dorsal valve 5 mm. in width has a length of 5.25 mm.

As far as may be determined from the casts, the outer surface is marked by concentric lines and striæ of growth, and the inner surface by radiating striæ and concentric lines of growth and scattered pits or punctæ. The shell appears to have been rather thick, and built up of a thin outer layer and numerous lamellæ that over the anterior two-thirds of the shell were oblique to the outer layer; the edges of the lamellæ show very plainly when the outer layer is removed.

The area of the ventral valve as shown by casts of the interior is of medium length, divided midway by a narrow elevated cast of the pedicle furrow, and again by a narrow flexure line about halfway between the pedicle groove and the lateral margin; striæ of growth cross it parallel with the base. The area of the dorsal valve is relatively long, with the flexure lines clearly defined. The interior markings shown in the cast of the ventral valve are the main vascular sinuses and the outline of the visceral area; in the dorsal valve only traces of the visceral area and main vascular sinuses have been observed.

Observations.—This species appears to be more nearly related to *Lingulella tarpa* (Walcott) than to any other of the Middle Cambrian forms. It is a smaller shell than *L. tarpa*, and less acuminate. It has the outline of some of the species of the Atlantic basin fauna such as *Lingulella radula* Matthew (Pl. XLV), but it does not appear to be specifically identical with any of them.

FORMATION AND LOCALITY.—**Middle Cambrian:** (13) Sandstones of the Rome formation, 1.5 miles (2.4 km.) east of Post Oak Springs [Hayes, 1894, areal geology sheet], Roane County; (13b) sandstones of the Rome formation, northeast of Rhea Springs [Hayes, 1894, areal geology sheet], Rhea County; and (11) sandstones and shales of the Rome formation, about 1 mile (1.6 km.) east of Post Oak Springs [Hayes, 1894, areal geology sheet], Roane County; all in Tennessee.

(13c) Sandstones of the Rome formation, west side of the sandstone ridge about 2.5 miles (4 km.) southwest of Rome [Hayes, 1902, historical geology sheet], Floyd County, Georgia.

LINGULELLA ? INSONS (Barrande).

Plate XXXII, figures 2, 2a-e.

Lingula insons BARRANDE, 1879, *Système silurien du centre de la Bohême*, vol. 5, Pl. CV, figs. x: 1-6. (Not described, but figured as a new species. Pl. CV, figs. x: 4A, 3A, 5A, 6A, 6E, and 1f are copied in this monograph, Pl. XXXII, figs. 2, 2a-e, respectively.)

This is one of the forms that, in the character of the area of the ventral valve, suggests both *Lingulella* and *Lingula*. It is introduced more to call the attention of students to the type than as a representative of the genus *Lingulella*. It is possible that it may belong to the subgenus *Leptembolon* of Mickwitz.

FORMATION AND LOCALITY.—Lower Ordovician: (303d) Étage d1, at Swarow; and (303e) Étage d1 at Sta. Benigna; both [Barrande, 1879b, Pl. CV] in Bohemia, Austria-Hungary.

LINGULELLA IOLE (Billings).

Plate XXVII, figures 5, 5a.

Lingula iole BILLINGS, 1865, *Geol. Survey Canada, Paleozoic Fossils*, vol. 1, p. 215, figs. 199a-e. (Described as a new species. The two specimens represented by figs. 199a-e are redrawn in this monograph, Pl. XXVII, figs. 5 and 5a.)

The type specimens of this species sent to me by Prof. J. F. Whiteaves included single specimens of the ventral and dorsal valves showing only the outer surface, and, where that is exfoliated, the surface of the inner layers or lamellæ. The surface is marked by very fine concentric striæ and lines of growth and very fine, obscure, radiating striæ upon the outer surface which are slightly more marked on the inner layers. The edges of the lamellæ indicate that the shell was of moderate thickness, less so than that of *Obolus cyane* (Billings). The ventral valve has a length of 7.5 mm.; width, 5 mm.; the dorsal valve is 6 mm. in length and 4.5 mm. in width.

This species is associated with *Obolus cyane* and belongs to the same group of species, so far as can be judged from the external form and appearance of the shell.

The stratigraphic horizon appears to correspond with the upper portion of the Chazy and base of the Trenton, of the New York section.

FORMATION AND LOCALITY.—Lower Ordovician: (314d) Limestone of Division P [Billings, 1865a, p. 215] of the "Quebec group," 4 miles (6.4 km.) northeast of Portland Creek, Newfoundland.

LINGULELLA IRENE (Billings).

Plate XXVII, figures 6, 6a.

Lingula irene BILLINGS, 1862, *Geol. Survey Canada, Paleozoic Fossils*, vol. 1, pp. 71-72, figs. 64a-b. (Described as a new species. The specimens represented by figs. 64a-b are redrawn in this monograph, Pl. XXVII, figs. 6a and 6, respectively.)

Lingula irene BILLINGS, 1863, *Geol. Survey Canada, Fifteenth Rept. Progress*, p. 230, figs. 240a-b. (No text reference. Figures copied from previous reference.)

Lingulella irene (Billings), SCHUCHERT, 1897, *Bull. U. S. Geol. Survey No. 87*, p. 257. (Merely changes generic reference.)

General form subovate; broadly rounded in front with the ventral valve subacuminate and the dorsal valve rounded at the beak. Surface of shell marked by concentric lines and striæ of growth and fine radiating striæ. The specimens are almost flattened in the shale and the substance of the shell has been very largely removed, so that it is impossible to determine the markings upon the surface, the layers of which it may have been formed, or its thickness. A thickened rim on the ventral valve indicates that the shell was strong and probably built up as in other species of *Lingulella*. The type specimen, the ventral valve, as compressed in the shale, has a length of 16.5 mm., with a maximum width of 13.25 mm. The dorsal valve is 15.5 mm. in length and 14 mm. in width.

The area of the ventral valve is strongly marked and relatively long. It is divided midway by a clearly defined pedicle furrow and toward the lateral margins by sharp flexure lines. Fine

striæ of growth cross the area and the pedicle furrow parallel to its base. The area of the dorsal valve is partly shown in the figured specimen. It is rather long and marked by numerous fine transverse striæ. The only interior markings preserved are traces of the main vascular sinus in the ventral valve and a portion of the narrow ridge on each side of the central groove of the vascular cavity.

Observations.—This is a large fine species that occurs in the siliceous slates at Point Levis. It may be compared with the Lower Ordovician species, *Obolus selwyni* (Matthew) and *Lingulella (Lingulepis) roberti* (Matthew).

Billings [1862b, p. 72] states that a single valve, found in the "Calciferous sandrock" at the eastern end of the island of Montreal, is rather strongly convex, especially on the umbonal.

FORMATION AND LOCALITY.—Lower Ordovician: (319a [Billings, 1862b, p. 72]) Levis shales, Point Levis, Quebec, Canada.

LINGULELLA IRIS (Billings).

Plate XXVII, figure 2.

Lingula iris BILLINGS, 1865, Geol. Survey Canada, Paleozoic Fossils, vol. 1, p. 301, fig. 290. (Described as a new species, see below for copy. The specimen represented by fig. 290 is redrawn in this monograph, Pl. XXVII, fig. 2.)

The original description by Billings follows:

Shell small, subovate; sides parallel, or nearly so, in the lower two-thirds gently convex or somewhat straight; in the upper one-third converging to the beak with a convex slope; beak narrowly rounded; anterior angles rounded; anterior margin, with a portion in the middle, somewhat straight. The only specimen collected is gently convex, a somewhat flat space along the middle, and a flat or gently convex slope on each side to the margin in the upper two-thirds. Surface with obscure radiating and concentric striæ. Length, $4\frac{1}{2}$ lines; width, $3\frac{1}{4}$ lines.

The only specimen of this species in the collection of the Geological Survey of Canada is the one described by Billings [1865a, p. 301]. It is a dorsal valve with an outline somewhat like that of *Lingulella arguta* (Walcott) [Pl. XXIV, fig. 5a].

The character of the limestone matrix and the small fragments of trilobites embedded in it indicate that the specimen was taken from one of the boulders of Cambrian limestone embedded in the Ordovician limestone No. 2 of the Point Levis section [Walcott, 1890a, p. 111].

FORMATION AND LOCALITY.—Upper Cambrian: (319d [Billings, 1865a, p. 301]) Limestone boulder in Lower Ordovician conglomerate, Point Levis, Quebec, Canada.

LINGULELLA ISSE (Walcott).

Text figures 43A-F, page 510, and Plate XXXIX, figures 4, 4a-b.

Obolus (Lingulella) isse WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 330. (Characterized as a new species.)

This shell is rather strong and made up of several thin layers or lamellæ. Its outer surface is marked by concentric lines of growth, sometimes grouped in more or less elevated bands, and over all there is a thin encrusting or scabrous layer that has a minutely granular, dull surface, somewhat like that of *Lingulella (Lingulepis) gregwa* (Matthew), but very much finer in its granulations or points. The inner layers of the shell are dark, shiny, and marked by concentric lines of growth and radiating striæ.

The longest ventral valve has a length of 16 mm. The proportions of length and breadth of the valves are as follows:

Dimensions, in millimeters, of valves of Lingulella isse (Walcott).

| | | Length. | Width. |
|---------------------|-----------------------|---------|--------|
| Ventral valves..... | {Elongate..... | 16 | 9 |
| | {Medium..... | 10 | 7 |
| | {Short and broad..... | 11 | 9 |
| Dorsal valves..... | {Elongate..... | 6.5 | 4.5 |
| | {Medium..... | 5 | 4.5 |
| | {Short and broad..... | 11 | 8.5 |
| | | 10.5 | 9 |

Observations.—The ventral valves of *Lingulella isse* have an outline very similar to that of *Lingulella pogonipensis* (Walcott) and *L. acutangula* (Roemer) (Pl. XVII), but the dorsal valves are more subquadrate in outline, and even the elongate form of the dorsal valve is more obtusely rounded. The species has a considerable vertical distribution in the House Range section. It is first met with 950 feet (289.6 m.) above the Middle Cambrian, and again at the 1,150 (350.5 m.) and 1,400 foot (426.7 m.) horizons. Fragments of a closely allied species occur near the summit of the Upper Cambrian, 2,800 feet (853.4 m.) above the Middle Cambrian, and a single dorsal valve was collected from the Weeks limestone of the Middle Cambrian, 650 feet (198 m.) below the base of the Upper Cambrian. If these two somewhat doubtful, but still closely allied, shells are identical the known vertical range of the species is 3,450 feet (1,052 m.), a range that may be compared with that of *Obolus mcconnelli* (p. 397) and *L. desiderata* (p. 493).

The original description of the species [Walcott, 1905a, p. 330] referred it to the Middle Cambrian, but later collections from the House Range section show this reference to have been incorrect, as the associated fauna occurs in the Orr formation 30 miles to the south.

FORMATION AND LOCALITY.—**Upper Cambrian:** (15d)^a *Thin-bedded blue limestone near Cave Spring on the east side of the Fish Spring Range, about 4 miles (6.4 km.) south of the J. J. Thomas ranch; and (33d) thin-bedded blue limestone from the same horizon as locality No. 15d at the base of the first high point southwest of the J. J. Thomas ranch, on the east side of the Fish Spring Range; both in Juab County, Utah.*

(30j) 950 feet (289.6 m.) above the Middle Cambrian and 2,450 feet (746.8 m.) below the top of the Upper Cambrian, near the base of the arenaceous shales and limestone forming 1e of the Orr formation [Walcott, 1908f, p. 176], on Orr Ridge, about 5 miles (8 km.) south of Marjum Pass; (30k) 1,150 feet (350.5 m.) above the Middle Cambrian and 2,175 feet (662.9 m.) below the top of the Upper Cambrian, at the top of the arenaceous shales and limestones forming 1e of the Orr formation [Walcott, 1908f, p. 176], on Orr Ridge, about 5 miles (8 km.) south of Marjum Pass;

FIGURE 43.—*Lingulella isse* (Walcott). A, Ventral valve flattened and distorted in the shale (U. S. Nat. Mus. Cat. No. 51809a). B, Dorsal valve flattened in the shale (U. S. Nat. Mus. Cat. No. 51809b). C, C', Ventral valve (U. S. Nat. Mus. Cat. No. 56998a). D, D', Dorsal valve (U. S. Nat. Mus. Cat. No. 56998b). E, Dorsal valve (U. S. Nat. Mus. Cat. No. 56998c). F, Young shell tentatively referred to this species (U. S. Nat. Mus. Cat. No. 56998d).

The specimens represented by figures 43A and 43B are from Locality 30k; those represented by figures 43C, 43D, 43E, and 43F are from Locality 30j; both in the Upper Cambrian limestones of the Orr formation, House Range, Millard County, Utah.

(30y) about 1,400 feet (426.7 m.) above the Middle Cambrian and 1,900 feet (579.1 m.) below the top of the Upper Cambrian in the supposed metamorphosed equivalent of the shales forming 1b of the Orr formation [Walcott, 1908f, p. 176], above the granite contact on top of the ridge north of Notch Peak; (31q) about 2,800 feet (853.4 m.) above the Middle Cambrian and 500 feet (152.4 m.) below the top of the Upper Cambrian in the gray limestone forming 1a of the Notch Peak limestone [Walcott, 1908f, p. 175], on the north slope of Notch Peak; all in the House Range [Walcott, 1908f, Pls. XIII and XIV], Millard County, Utah.

(34r and 34t) Limestone 1.5 miles (2.4 km.) northwest of Wahwah Springs, on the north side of the road at Cane Pass, Wahwah Mountains, Beaver County; (32g) about 2,575 feet (784.9 m.) above the Cambrian quartzitic sandstones in a blue limestone about 2 miles (3.2 km.) southeast of Muskrat Spring, on the northwest face of Grantsville Peak, Stansbury Range, Tooele County; and (30s) green shale about 1,200 feet (365.8 m.) above the Cambrian quartzitic sandstones on the pipe line above the limekiln in Ogden Canyon 1 mile (1.6 km.) above its mouth, east of Ogden, Weber County; all in Utah.

(313) Limestone 0.75 mile (1.2 km.) east-northeast of McGill post office, White Pine County, Nevada.

(57d) About 3,215 feet (980 m.) above the Middle Cambrian and 375 feet (114.3 m.) below the top of the Upper Cambrian in green shales near the summit of 2b of the Sherbrooke limestone [Walcott, 1908f, p. 204], on ridge west of Mount Bosworth, on the Continental Divide between Alberta and British Columbia, just north of the Canadian Pacific Railway, Canada.

^a The species also occurs in Locality 34i (p. 196).

Middle Cambrian: (30n) About 3,750 feet (1,143 km.) above the Lower Cambrian and 650 feet (198 m.) below the Upper Cambrian in the shaly limestones forming 1c of the Weeks limestone [Walcott, 1908f, p. 175], on the north side of Weeks Canyon, about 4 miles (6.4 km.) south of Marjum Pass, House Range [Walcott, 1908f, Pl. XIII], Millard County; and (31y) thin-bedded limestone about 125 feet (38 m.) above the Cambrian quartzitic sandstones, in the Wasatch Mountains, 1 mile (1.6 km.) northwest of Geneva, east of Brigham, Boxelder County; both in Utah.

(54s) Dark blue-gray Langston limestone [Walcott, 1908f, p. 198], just above the Cambrian quartzitic sandstones, north side of Twomile Canyon, near its mouth, 2 miles (3.2 km.) southeast of Malade, Oneida County, Idaho.

(57n)^a About 3,000 feet (914.4 m.) above the Lower Cambrian and about 700 feet (213.4 m.) above the base of a limestone correlated with No. 4 of the Eldon limestone on Mount Bosworth [Walcott, 1908f, p. 209], on the northwest slope of Mount Stephen, above Field on the Canadian Pacific Railway, British Columbia.

LINGULELLA KIURENSIS (Waagen).

Plate XXX, figures 5, 5a, 6, 6a.

Lingula? kiurensis WAAGEN, 1885, Mem. Geol. Survey India, Paleontologia Indica, 13th ser., Salt Range Fossils, vol. 1, pt. 4, fas. 5, pp. 768-769, Pl. LXXXVI, figs. 8a-b. (Described and discussed as a new species, see below.

The specimen represented by figs. 8a-b is redrawn in this monograph, Pl. XXX, fig. 6.)

Lingula? warthi WAAGEN, 1885, idem, pp. 769-770, Pl. LXXXVI, figs. 9a-b. (Described and discussed as a new species. The specimen represented by figs. 9a-b is redrawn in this monograph, Pl. XXX, fig. 5.)

Lingula? kiurensis WAAGEN, 1891, idem, vol. 4, pt. 2, Pl. II, figs. 17a-b. (No text reference. Figures copied from those representing *L. warthi* Waagen, 1885, Pl. LXXXVI, figs. 9a and 9b. Figures 17a-b are reproduced in this monograph, Pl. XXX, fig. 5a.)

Lingula? warthi WAAGEN, 1891, idem, vol. 4, pt. 2, Pl. II, figs. 18a-b. (No text reference. Figures copied from those representing *L. kiurensis* Waagen, 1885, Pl. LXXXVI, figs. 8a and 8b. Figs. 18a-b are reproduced in this monograph, Pl. XXX, fig. 6a.)

Through the courtesy of the director of the Geological Survey of India, Mr. T. H. Holland, I have had the opportunity of studying the type specimens of the two species described by Waagen. Of *Lingulella kiurensis*, Waagen mentions [1885, p. 769] that he had a single specimen, which he considered to be a ventral valve. He also had but one specimen of the second species, "*Lingula? warthi*," which he could not decide as either a ventral or dorsal valve. I find that the two specimens are from the same locality and from the same bed of rock. Waagen stated [1885, p. 770] that he long considered them as belonging to the same species, but owing to the existence of a "reticulation" on the lateral parts of "*L.? warthi*" he decided to separate the latter as a distinct species. In a reflected light I find traces of the "reticulation" on the outer portions of *L. kiurensis*, and it is quite common in an arenaceous matrix to find shells from which the finely reticulated outer surface has been abraded. My interpretation of the two specimens is that they represent one species, and that Waagen's type of "*Lingula? warthi*" is the ventral valve and the type of his "*Lingula? kiurensis*" the dorsal valve. Carefully made drawings have been prepared of the two type specimens, and beside them are reproduced the somewhat diagrammatic figures accompanying Waagen's description.

In 1891 Waagen refigured [1891, Pl. II, figs. 17a-b] the specimen which he described in 1885 [1885, p. 769] as "*Lingula warthi*" and labeled it "*Lingula? kiurensis*." Similarly, the specimen which he described [1885, p. 768] as "*Lingula? kiurensis*" is [1891, Pl. II, figs. 18a-b] labeled "*Lingula? warthi*."

The original description by Waagen follows:

The general form of the shell is an elongate oval with the ventral valve slightly more acuminate than the dorsal; original convexity unknown, as both specimens are flattened in the matrix and one is slightly crushed. Surface marked by round striæ of growth that vary in size, and a few narrow, irregular, rounded, radiating ribs on the sides.

Waagen [1885, p. 768] described this species under the impression that it was from the *Productus* limestone of the Carboniferous. Subsequently, this view was modified on account of the discovery of Cambrian fossils by Warth. The history of the discoveries and discussion is very clearly presented by Noetling [1894, pp. 71-86] in an article on the "Cambrian formation of the Salt Range."

The first impression made by this shell when comparing it with other species of *Lingulella* is that it is an Upper Cambrian type. Its broad oval outline is not unlike that of *Lingulella*

^a The species is somewhat doubtfully identified from this locality.

bella (Walcott), of Newfoundland, *Lingulella davisi* (McCoy), of Wales, *L. mosia osceola* (Walcott), and *Obolus* (*Westonia*) *stoneanus* (Whitfield), of Wisconsin. No such forms are known to me from the Lower Cambrian, and the broad shells from the Middle Cambrian are usually more acuminate.

The specific name is derived from Kiura, the type locality.

FORMATION AND LOCALITY.—Middle Cambrian: (357 [Waagen, 1885, p. 769]) Limestones in the “*Neobolus* beds” of the Khussak group; above the salt mines at Kiura (Khewra), Salt Range, India.

LINGULELLA LÆVIS Matthew.

Plate XIX, figures 4, 4a-b.

Lingulella lævis MATTHEW, 1892, Trans. Roy. Soc. Canada for 1891, 1st ser., vol. 9, sec. 4, No. 5, p. 39, Pl. XII, figs. 4a and 4b. (Described as a new species, see below for copy. The specimens represented by figs. 4a and 4b are redrawn in this monograph, Pl. XIX, figs. 4a and 4, respectively.)

The original description by Matthew follows:

A large oval-ovate species, with a very thin test, resembling a *Lingula* in its thin hinge line, and having a pedicle groove.

The shell has a smooth, shining surface, but when observed with a lens very fine concentric and fainter radiating lines are made visible.

Ventral valve, length, 15 mm.; width, 11 mm. Dorsal valve, length, 14 mm.; width, 11 mm. Another dorsal valve is 17 mm. long and 15 mm. wide.

This is a very interesting species on account of the thinness of the shell and the unusual outline of the dorsal valve. It is unfortunate that the material for study does not show the interior of the valves.

FORMATION AND LOCALITY.—Upper Cambrian: (301n) Shales of Division C3a of Matthew [1892, p. 39], on the right shore below the “falls,” St. John Harbor, St. John County, New Brunswick.

LINGULELLA LÆVIS GRANDIS Matthew.

Plate XIX, figure 4c.

Lingulella lævis grandis MATTHEW, 1903, Geol. Survey Canada, Rept. Cambrian Rocks Cape Breton, pp. 200–201, Pl. XV, figs. 1a–d. (Described and discussed as a new variety. The specimen represented by fig. 1d is redrawn in this monograph, Pl. XIX, fig. 4c.)

Matthew considers this shell a variety of *Lingulella lævis*. It is somewhat larger, but a good series of specimens would probably unite the two forms. Matthew [1903, p. 201] gives a very elaborate description of the interior of the valves. He sent me the type of the dorsal valve, which is illustrated (fig. 4c). I could not discover many of the markings indicated in his illustration, but the latter may be a composite drawing.

FORMATION AND LOCALITY.—Upper Cambrian: (325b [Matthew, 1903, desc. of Pl. XV]) Sandy shales of Division C3a of Matthew, at Escasonie shore, East Bay, east of Bras d'Or Lake, in eastern Cape Breton, Nova Scotia.

(301t [Matthew, 1903, p. 201]) Sandy shales of Division C3a of Matthew, at Carlton shore, near the suspension bridge, St. John, St. John County, New Brunswick.

LINGULELLA LENS (Matthew).

Plate XXXIII, figures 1, 1a–d.

Lingula ? lens MATTHEW, 1901, Bull. Nat. Hist. Soc. New Brunswick, vol. 4, pt. 4, No. 19, pp. 274–275, Pl. V, figs. 3a–h, (Described and discussed as a new species. The specimen represented by fig. 3a is redrawn in this monograph, Pl. XXXIII, fig. 1.)

Obolus (*Lingulella*) *bellus* WALCOTT (in part), 1901, Proc. U. S. Nat. Mus., vol. 23, pp. 685–687. (Matthew's “*Lingula lens*” is here described with, and referred to, “*Obolus* (*Lingulella*) *bellus*.”)

Obolus (*Lingulella*) *lens* (Matthew), WALCOTT, 1902, idem, vol. 25, pp. 606–607. (Described and discussed as a distinct species.)

Lingulella lævis lens MATTHEW, 1903, Geol. Survey Canada, Rept. Cambrian Rocks Cape Breton, pp. 201–203, Pl. XV, figs. 3a–h. (Matthew's original “*Lingula ? lens*” is here described and discussed as a variety of *Lingulella lævis*. The description is an essential copy of and the figures are copied from Matthew, 1901, pp. 274–275, Pl. V, figs. 3a–h.)

Lingulella lens MATTHEW, 1903, idem, pp. 205–206. (Discussed as not belonging under *Westonia*.)

Not *Obolus (Palæobolus) lens* MATTHEW, 1903, Geol. Survey Canada, Rept. Cambrian Rocks Cape Breton, pp. 144-146, Pl. X, figs. 1a-f. (Referred in this monograph to *Obolus (Palæobolus) bretonensis lens*.)

General form broadly ovate. The ventral valve is subacuminate and the dorsal valve very broadly ovate to subsemicircular. The convexity of the valves is moderate, the ventral valve being most prominent along the center, with the posterolateral slopes somewhat flattened toward the margin.

Surface of the shell marked by fine, concentric striæ and lines of growth, and the inner surface by concentric lines and very fine radiating striæ. The shell is thinner than most species of the genus, resembling in this respect *Obolus? murrayi* Billings, *Lingulella lævis* Matthew, and *L. bella* (Walcott). It is formed of several layers or lamellæ that are slightly oblique to the outer layer. Matthew [1901, p. 274] speaks of minute pits on the outer surface. These also appear on the inner layers. I have been unable to determine whether the thin calcareous crust mentioned by Matthew [1901a, p. 274] is really the true outer layer or simply a thin calcareous deposit.

The largest specimen of a dorsal valve in the collection has a length of 15 mm., with a width of 13 mm. The corresponding ventral valve was probably 1 or 2 millimeters longer.

Observations.—In the material collected by Loper in 1901 there are some specimens that show the form of the ventral and dorsal valve of this species. The shell is broader and rounder than I supposed when studying the material Matthew sent me. It is quite distinct from *Lingulella bella* (Walcott) and *L. concinna* Matthew, with which I placed it. The interior markings are those of *Lingulella*, but it may be that more perfect material would prove it to belong to one of the subgenera of *Obolus*.

Matthew [1903, p. 201] refers to this form as a variety of *Lingulella lævis*. With the material from Cape Breton and Newfoundland for comparison, I am not sufficiently sure to follow him in this, as it appears to be specifically distinct from *lævis*.

Further remarks on this species occur under *Lingulella concinna* (p. 487).

FORMATION AND LOCALITY.—Upper Cambrian: (10r)^a Thin calcareous layers in the arenaceous shales of Division C3a? of Matthew at McAdam shore, East Bay, east of Bras d'Or Lake, eastern Cape Breton, Nova Scotia.

LINGULELLA LEOS (Walcott).

Plate XXIV, figures 2, 2a-c.

Obolus (Lingulella) leos WALCOTT, 1898. Proc. U. S. Nat. Mus., vol. 21, p. 407-408. (Described and discussed essentially as below as a new species.)

Shell small; general form elongate ovate with the ventral valve subacuminate. The valves are rather strongly convex in the narrow form of the species. Average length of a ventral valve is 5 mm.; the largest ventral valve has a length of 6 mm.; the dorsal valve is somewhat shorter. The width of the valve varies considerably in shells occurring in the same hand specimens in the limestone. This is shown by Plate XXIV, figures 2 and 2a, for the ventral valve, and 2b and 2c for the dorsal valve. The surface of the shell is marked by fine concentric lines and striæ of growth, and very fine, interrupted, radiating striæ; casts of the interior of the shell show stronger radiating striæ than the outer surface; also in many specimens unusually large papillæ that fill the pits or punctæ of the inner surface. The number and strength of the papillæ vary in different casts. The shell appears to have been rather thin, and formed of a thin outer layer and one or more thin inner layers or lamellæ.

Casts of the interior of the ventral valve show a well-defined area, divided midway by the cast of a strong pedicle groove. The area of the dorsal valve is obscured by adhering fragments. On casts of the ventral valve traces of the visceral cavity (v) and the main vascular sinuses (vs) occur, and in the dorsal a narrow, long median sinus is clearly defined; also the casts of the central and anterior lateral muscle scars (Pl. XXIV, figs. 2b and 2c).

^a10r is the type locality, though the specimens in the United States National Museum collections to which that number is assigned were collected later than the type specimens.

Observations.—This neat little species in some respects resembles *Lingulella similis* (Walcott). It differs, as may be seen by comparing Plate XXIV, figures 2, 2a-c, with Plate XXI, figures 2, 2a-c, in being more elongate, the interior more strongly punctate, and in the more anterior position of the central muscle scars in the dorsal valve.

FORMATION AND LOCALITY.—Upper Cambrian: (96) Limestones near the ford on the Cedartown road, 1.5 miles (2.4 km.) south of Rome, Floyd County, Georgia.

I was in doubt about this species until after studying a fine series of specimens collected for me by Schmalensee at various localities in Sweden. The Swedish shells, in a limestone matrix, have a broader outline than the typical forms of *Lingulella ferruginea*, in a limestone matrix, although some of the latter are as broad when flattened in the matrix. When the shells of *L. lepis* are compressed laterally they look very much like those of *L. ferruginea* Salter. Under like conditions of preservation they appear to be distinct. The interior surface is marked by concentric lines of small pits. The outer surface varies from an almost smooth and polished surface marked by concentric lines of growth to a broken surface marked by concentric lines and radiating, more or less irregular, raised ribs. All the characters known are illustrated on Plate XXXI.

The American representative of this species, *Lingulella bella* (Walcott), which has a stratigraphic range similar to that of the shell from Wales, from the Upper Cambrian into the Lower

Ordovician, appears to be a much larger shell. In Norway and Sweden it occurs in the *Ceratopyge* limestone. Compressed and flattened shells from the *Paradoxides davidis* zone of Manuels Brook, Newfoundland, strongly suggest this species, but no similar forms occur in the calcareous layers interbedded in the shales, although *L. ferruginea* Salter is abundant in both limestone and shale.

Moberg and Segerberg [1906, pp. 62–63] have described and illustrated five species of small *Lingulella*-like shells from the *Ceratopyge* zone of Sweden. The form illustrated as *Lingulella lepis* (Salter) [Moberg and Segerberg, 1906, Pl. I, fig. 20] is a dorsal valve of that species from the *Dictyograptus* zone. The form given the name *Lingula? corrugata* Moberg and Segerberg [1906, Pl. I, fig. 21] is from the lower portion of the *Dictyograptus* zone and appears to be a partly exfoliated dorsal valve of *L. lepis*. Of the remaining two species, the one named *Lingula? ordovicensis* Moberg and Segerberg [1906, Pl. I, fig. 24] is much like the ventral valve of *L. lepis* as illustrated on Plate XXXI, figure 4b, of this work, and the other, *Lingula? producta* Moberg and Segerberg [1906, Pl. I, fig. 23], appears to be a similar shell laterally compressed. I have a series of specimens from the *Ceratopyge* limestone of Norway and Sweden that indicate that the species had a considerable range of variation, in this respect resembling *L. ferruginea* Salter (Pl. XXIX, figs. 1 and 2); in fact the variations of the latter species nearly include the forms referred to *L. lepis* (Pl. XXXI, figs. 4, 4a–f). It may be that Moberg and Segerberg's specific names should be retained, but with the information now available I am inclined to consider them all as synonyms of *L. lepis*.

The specific name is derived from *λεπίς*, a scale.

FORMATION AND LOCALITY.—**Passage beds** from the Upper Cambrian to the Ordovician: (8x) *Ceratopyge* limestone at Slemmestad, about 3 miles (4.8 km.) southwest of Christiania; (323f and 323h [Brögger, 1882, pp. 16–17]) *Ceratopyge* limestone at Vestfossen, 10 miles (16.1 km.) west-southwest of Christiania; and (323c [Brögger, 1882, p. 44]) *Ceratopyge* limestone in the Christiania region; all in Norway.

(320w [Holm, 1898, p. 148]) *Ceratopyge* limestone at Glöte in Herjeådalen, Province of Jemtland; (310 [Moberg and Segerberg, 1906, p. 63]) *Ceratopyge* limestone (zone 4) at Ottenby, Oeland Island; (310j) *Ceratopyge* limestone at Borgholm, Oeland Island; (310w [Westergård, 1909, desc. of Pl. II]) zone c at Grönhögen, Oeland Island; and (309 [Moberg and Segerberg, 1906, p. 63]) *Ceratopyge* limestone (zone 4) at Fogelsång, 5 miles (8 km.) east of Lund, Province of Malmöhus; all in Sweden.

Upper Cambrian: (9f) Limestones of the *Olenus* zone at Nørnsnæs, west of Christiania; and (323a [Wiman, 1902, p. 66]) *Ceratopyge* slate in the Christiania region; both in Norway.

(3211^b and 321m^b) Drift boulders of *Ceratopyge* slate, Nos. 14, 17, and 27 [Wiman, 1902, p. 68], on Biludden, about 20 miles (32.2 km.) east of Gefle, Province of Gefleborg; (309a [Moberg and Segerberg, 1906, p. 62]) *Bryograptus* slate (zone 2) at Fogelsång, 5 miles (8 km.) east of Lund, Province of Malmöhus; (310d) *Ceratopyge* slate at Borgholm, Oeland Island; and (309b [Moberg and Segerberg, 1906, p. 63]) *Dictyograptus* slate (zone 1) at Flagabro, Province of Malmöhus; all in Sweden.

(305a [Davidson, 1866, desc. of Pl. III]) Upper Tremadoc beds at Moel-y-gest, northwest side, Carnarvonshire; (366q [Davidson, 1866, p. 54]) Upper Tremadoc beds at Garth, opposite Portmadoc, Merionethshire; (305e [Davidson, 1866, p. 54]) Upper Tremadoc beds near Tai-hirion, Arenig; (305c) Lower Tremadoc slate, everywhere in the Tremadoc district, Carnarvonshire; (305d)^{a b} Upper *Lingula* flags near Tremadoc, Carnarvonshire; (305f)^a Lower Tremadoc, east of Port Nant-y-Ladron, on the Bala Road from Ffestiniog, Merionethshire; (305g)^a Lower Tremadoc at Wern; (305h)^a Lower Tremadoc at Borthwood; (305i)^a Lower Tremadoc at Trwyn-y-Iago; and (305j)^a Lower Tremadoc at Cefn Cyfar-nedd; all in North Wales.

(307a [Matthew, 1903, p. 240])^b Shales of Division C3c2 of Matthew, on McLeod Brook (=Barachois River), near Boisdale, eastern Cape Breton, Nova Scotia, Canada.

(301e)^b Beds of Division C3a of Matthew; and (301u) shales of Division C3b of Matthew; both [Matthew, 1903, p. 204] in the St. John Basin, St. John County, New Brunswick, Canada.

LINGULELLA LINEOLATA (Walcott).

Plate XLVIII, figures 2, 2a–l.

Obolus (*Lingulella*) *lincolatus* WALCOTT, 1898, Proc. U. S. Nat. Mus., vol. 21, pp. 408–409. (Described and discussed essentially as below as a new species.)

General form ovate, with the ventral valve subacuminate, and the dorsal valve ovate to broad ovate. The range of variation in the outline of the valves is quite strongly marked; this

^a Davidson, 1866, p. 54.

^b The species is somewhat doubtfully identified from this locality.

may be seen by comparing Plate XLVIII, figures 2a, 2e, 2i, and 2k of the ventral valve and figures 2b, 2c, 2d, 2f, and 2g of the dorsal valve. The convexity of the valves is moderate, that of the dorsal valve being a little more than that of the ventral (fig. 2j).

The surface of the shell is marked by concentric lines and striae of growth, with very fine, concentric striae between them that are sometimes slightly undulating; on some specimens very faint radiating striae can be seen with a strong lens; when the outer layer is exfoliated the inner layer is marked by fine radiating and concentric striae in addition to the stronger concentric striae; as far as can be determined from the imperfect casts of the interior the inner surface of the shell was nearly smooth. The shell appears to be formed of a very thin outer layer and one or more thin inner layers or lamellae; toward the frontal margins the oblique lamellae increase in number, but do not give any considerable thickness to the shell.

One of the largest of the ventral valves referred without doubt to this species has a length of 7 mm. and a width of 5.5 mm. An associated dorsal valve is slightly shorter in proportion to the width. The average size is smaller, not exceeding 5 mm. for the length of the ventral valve. One unusually large ventral valve that is referred to this species with some doubt has a length of 9 mm.

The only traces of the interior of the shell that have been observed are portions of the cardinal area and pedicle furrow of the ventral valve (Pl. XLVIII, fig. 2j) and the cardinal area of a dorsal valve (Pl. XLVIII, figs. 2f and 2l).

Observations.—This species is very abundant in the upper beds of the "Tonto" sandstone. It is associated with *Obolus* (*Westonia*) *euglyphus* (Walcott), and it is often difficult when the two are in the form of imperfect casts, to distinguish between the larger specimens of the two species. They are readily distinguished, when the shells are well preserved, by the difference in surface markings and the more acuminate ventral valves of *Lingulella lineolata*. The latter character, however, is not always of service, especially in the larger shells. In form the ventral valve of this species may be compared with *L. acutangula* (Roemer) (Pl. XVII).

FORMATION AND LOCALITY.—Middle Cambrian: (90) Siliceous limestone about 15 feet (4.5 m.) above the Coronado quartzite [Lindgren, 1905, p. 3], 0.5 mile (0.8 km.) southwest of Milk ranch, on the first spur north of the one which the main road follows; and (358) argillaceous shale, 50 feet (15.2 m.) above the Coronado quartzite [Lindgren, 1905, p. 3], west side of Chase Creek Canyon, 1.5 miles (2.4 km.) east-northeast of Morenci; both in the Clifton quadrangle (U. S. Geol. Survey), Graham County, Arizona.

(73) Sandstones of the Tonto group, in Kwagunt Valley; (73a) sandstones of Tonto group, in Chuar Valley; (74) sandstone about 300 feet (91.4 m.) above the base of the Tonto group, at the head of Nunkoweap Valley; (74d) sandstone beds in "Tonto" shale, just above massive sandstones near the mouth of Bass Canyon, on the south side of the Grand Canyon, southeast of Powell Plateau; and (17c) sandy limestone 235 feet (71.6 m.) above the "Tonto" sandstone, Grand View trail, north of Last Chance copper mine, south side of the Grand Canyon; all in the Grand Canyon of the Colorado, Arizona.

LINGULELLA LINNARSSONI (Walcott).

Plate XXX, figures 14, 14a.

Obolus (*Lingulella*) *linnarssoni* WALCOTT, 1901, Proc. U. S. Nat. Mus., vol. 23, p. 688. (Described as below as a new species.)

Ventral valve elongate oval, subacuminate. Surface marked by fine, undulating, depressed, radiating, ridgelike lines; closely undulating, concentric striae; and very fine papillae that appear to terminate in fine sharp points; the papillae are situated on the narrow, irregular, elevated spaces between the striae. Shell relatively thin and formed of several lamellae more or less oblique to the outer surface.

Observations.—The species is based on a fine specimen of a ventral valve associated with *Billingsella lindströmi* (Linnarsson) in the *Paradoxides* series of Lovén. It is broader than *Lingulella ferruginea* Salter and the surface ornamentation is quite different. The latter is more like that of the associated *Acrothele coriacea* Linnarsson. In outline it approaches more nearly to *L. lepis* (Salter).

The specific name was given in honor of Mr. J. G. Linnarsson.

FORMATION AND LOCALITY.—Middle Cambrian: (320n) Limestones of the *Paradoxides forchhammeri* zone at Lovén, Djupadal, 19 miles (30.6 km.) south-southeast of Skara, Province of Skaraborg, Sweden.

LINGULELLA MANTICULA (White).

Plate XX, figures 1, 1a-c.

Lingula? *manticula* WHITE (in part), 1874, U. S. Geog. Surveys W. 100th Mer.; Prelim. Rept. Invertebrate Fossils, pp. 9-10. (Described as a new species, including specimens referred to both *Lingulella manticula* and *L. arguta*.)

Lingula manticula WHITE (in part), 1877, U. S. Geog. Surveys W. 100th Mer., vol. 4, pt. 1, p. 52, Pl. III, fig. 2b (not fig. 2a). (Described essentially as in the preceding reference and discussed. The specimen represented by fig. 2b could not be located when the drawings of this species were being made, and the original drawing is reproduced in this monograph, Pl. XX, fig. 1c. The specimen represented by fig. 2a is referred in this monograph to *Lingulella arguta*.)

Not *Lingula?* *manticula* WALCOTT, 1884, Mon. U. S. Geol. Survey, vol. 8, pp. 13-14, Pl. IX, fig. 3; and Pl. XI, fig. 2. (These specimens are now referred to *Lingulella punctata*.)

Shell small, general form elongate ovate, with the ventral valve subaeuminate, and the dorsal valve ovate in outline. Valves rather strongly convex, the ventral being slightly more so along the posterior half than the dorsal. There is some variation in the outline of the valve, as is shown for the ventral by Plate XX, figures 1 and 1c, and for the dorsal by Plate XX, figures 1a and 1b.

Surface of shell marked by fine concentric lines of growth and very fine, slightly irregular concentric striæ; when the outer shell is partly exfoliated the outer surface of the inner layers is marked by fine, concentric lines and not very distinct radiating striæ; the inner surface of the shell shows concentric lines of growth and a few scattered pits or punctæ. The shell is of medium thickness and formed of a thin outer layer and one or more inner layers or lamellæ.

The average length of the ventral valve is 3.5 mm.; width, 2 mm. The associated dorsal valve of the same width has a length of 3 mm.

As shown in the cast of the interior of the shell the area of the ventral valve is long, clearly defined, and broken midway by a narrow but strong pedicle groove. It is also marked near its lateral margins by narrow flexure lines. The striæ of growth cross the area parallel with its base. They are very distinct but do not show on the cast of the pedicle furrow.

The cast of the interior of the ventral valve shows the visceral cavity (v) and the outline of the heart-shaped pit (x). In the dorsal valve sufficient is shown to indicate that the visceral cavity extended forward to about the middle of the shell, and that a narrow median septum was present.

Observations.—This is a small species that is representative of quite a group of somewhat similar forms that occur in the Upper Cambrian and Lower Ordovician faunas, both in the Rocky Mountain and Appalachian regions; *Lingulella punctata* (Walcott) representing the group in the Rocky Mountains, and *L. desiderata* (Walcott) in the Appalachian region.

Of the figures given by White [1877, Pl. III] figure 2b is taken as the type. Figure 2a of White [1877, Pl. III] is a larger shell, which I have referred to *L. arguta*. The specimens identified by Walcott [1884b, p. 13] as "*Lingula?* *manticula*" have been referred to *L. punctata*, as a comparison with the type of "*L.?* *manticula*" White shows them to be distinct.

This species was referred to the "Quebec group" by White [1874, p. 9], and it is probable that the horizon at which it occurs will be found to be in the passage beds between the Upper Cambrian and Lower Ordovician, or what corresponds to the lower part of the Pogonip limestone of the Eureka, Nevada, section. Since the preceding was written, Spurr collected a few Cambrian fossils in southern Nevada among which occurs a form that appears to be identical with *L. manticula*. The fragments of trilobites indicate a Cambrian fauna but not its stratigraphic horizon.

FORMATION AND LOCALITY.—**Lower Ordovician:** (202) Pogonip limestone, on the summit of the ridge directly southeast of the Jackson mine, northwest of Shadow Canyon, Eureka district [Hague, 1892. Atlas], Eureka County; and (214b) limestone near the middle of the Pogonip limestone, White Pine district, White Pine County; both in Nevada.

Upper Cambrian: (8e) Limestone in Patterson Canyon, west side of the Schell Creek Range; (313f) limestone at Schellbourne, Schell Creek Range, and (8f) limestone at summit of canyon, 10 miles (16.1 km.) south of Egan Canyon, east side of Egan Range; all in White Pine County, Nevada.

(61) Limestone in the Dunderberg shale [Walcott, 1908f, p. 184], a little south of the Hamburg mine; and (62) limestone in the Dunderberg shale [Walcott, 1908f, p. 184], in canyon immediately north of Adams Hill; both in the Eureka district [Hague, 1892, Atlas], Eureka County, Nevada.

(301) About 1,400 feet (426.7 m.) above the Middle Cambrian and 1,900 feet (579.1 m.) below the top of the Upper Cambrian in the shales forming 1b of the Orr formation [Walcott, 1908f, p. 176], on Orr Ridge, about 5 miles (8 km.) south of Marjum Pass [Walcott, 1908f, Pl. XIII], House Range, Millard County; (15d) thin-bedded blue limestone near Cave Spring, on the east side of the Fish Spring Range, about 4 miles (6.4 km.) south of the J. J. Thomas ranch, Juab County; (32f) thin-bedded siliceous limestone near the top of the Upper Cambrian, about 2 miles (3.2 km.) southeast of Muskrat Spring, on the northwest face of Grantsville Peak, Stansbury Range, Tooele County; and (30q) limestones about 2,300 feet (701 m.) above the Cambrian quartzitic sandstones on pipe line above limekiln, in Ogden Canyon, 1 mile (1.6 km.) above its mouth, east of Ogden, Weber County; all in Utah.

(54b) About 1,200 feet (365.8 m.) above the Middle Cambrian, and 25 feet (7.6 m.) below the top of the Upper Cambrian in the limestones forming 1 of the St. Charles formation [Walcott, 1908f, p. 191]; (31m) about 175 feet (53.3 m.) above the Middle Cambrian and 1,050 feet (320 m.) below the top of the Upper Cambrian, near the base of the limestones forming 3 of the St. Charles formation [Walcott, 1908f, p. 192]; and (54e) about 200 feet (61 m.) above the Middle Cambrian and 1,025 feet (212.4 m.) below the top of the Upper Cambrian, in limestones forming 3 of the St. Charles formation [Walcott, 1908f, p. 193]; all in Blacksmith Fork Canyon, about 10 miles (16.1 km.) east of Hyrum, Cache County, Utah.

Middle Cambrian: (7i) Limestone just west of the summit on the road east of Schellbourne, Schell Creek Range, White Pine County; and (7j) limestones at the north end of the Quinn Canyon Range, 1 mile (1.6 km.) northwest of the Italian Ranch foothills, Nye County; both in Nevada.

In the Nounan limestone in southern Idaho there is a narrow, elongate *Lingulella* that is closely allied to *L. manticula*. It differs in being narrower in proportion to the length, in this respect resembling *Lingulella cania* (Walcott) (Pl. XXXV, figs. 3, 3a-d) of Nova Scotia.

FORMATION AND LOCALITY.—**Middle Cambrian:** (56f) Nounan limestone [Walcott, 1908a, p. 6], in a ridge north of the creek which flows into Mill Canyon from the west, about 5 miles (8 km.) west-southwest of Liberty and 15 miles (24.2 km.) west of Montpelier, Bear Lake County, Idaho.

LINGULELLA MARTINENSIS Matthew

Plate XXXVIII, figures 1, 1a-g.

Lingulella dawsoni MATTHEW (in part) [not (WALCOTT)], 1886, Trans. Roy. Soc. Canada for 1885, vol. 3, sec. 4, No. 3, pp. 33-34, Pl. V, figs. 9, 9a-c (not fig. 9d). (Described and discussed as a new species, but refers in synonymy to Walcott, 1884a, p. 15. The specimen represented by figure 9d is referred in this monograph to *Lingulella ferruginea*.)

Lingulella martinensis MATTHEW, 1890, Trans. Roy. Soc. Canada for 1889, 1st ser., vol. 7, pp. 155-156, Pl. VIII, fig. 4. (Described as a new species.)

Lingulella martinensis MATTHEW, 1895, Trans. New York Acad. Sci. for 1894-5, vol. 14, pp. 113-114, Pl. II, figs. 6a-d. (Described and discussed. Fig. 6a is copied from fig. 4 of the preceding reference. The specimens represented by figs. 6b and 6d are redrawn in this monograph, Pl. XXXVIII, figs. 1d-e, and 1a, respectively. Figs. 1, 1b, 1c are also drawn from specimens in Matthew's type material, but further identification is impossible.)

Lingulella cf. *granvillensis* Walcott, MATTHEW, 1895, idem, pp. 114-115, Pl. II, figs. 7a and 7b. (Described and discussed.)

General form elongate ovate to subcuneate, with the ventral valve subacuminate, and the dorsal valve elongate ovate; the cardinal slopes of the ventral valve are nearly straight for fully one-half the length of the valve. Ventral valve moderately convex; dorsal valve unusually convex, especially over the umbonal region.

Surface of the shell marked by fine concentric lines of growth, and very fine, irregular raised striæ that form a surface of the type of that of *Lingulella radula* Matthew and *Lingulella* (*Lingulepis*) *roberti* (Matthew). The undulations cause the striæ to touch and blend so as to give the appearance of inosculation and a network of lines. The appearance of the surface markings often varies considerably on different portions of the same valve. The interior surface shows radiating lines and scattered punctæ. The shell is preserved largely as casts of the interior and exterior; it appears to have been built up of a thin outer layer and several inner layers or lamellæ.

The largest ventral valve received from Matthew has a length of 9 mm.; width, 6 mm. The area of the ventral valve is long and divided midway by a narrow, tapering pedicle groove, and toward the lateral margin by a well-marked flexure line. The area of the dorsal valve is unusually long and well marked; the flexure lines are strong and outline a broad, shallow groove between them (Pl. XXXVIII, fig. 1e).

A cast of the ventral valve shows a slight trace of the visceral cavity, also the anterior lateral muscle scars. A few outlines of the vascular markings are preserved in casts of the dorsal valve, also the transmedian and outside or middle lateral muscle scars which occur just within a narrow ridge that borders the somewhat flattened margin of the interior of the valve.

Observations.—The original figure of this species [Matthew, 1890, Pl. VIII, fig. 4] is quite unlike those subsequently given by Matthew [1895a, Pl. II]. The first type must have been distorted, or else it is a different species.

With original specimens to compare and study I consider the specimens referred to *Lingulella* cf. *granvillensis* by Matthew [1895a, p. 114] to be identical with *L. martinensis*. The size and form of the valves, convexity, and surface markings all serve to strengthen this conclusion. The ventral valve, figured by Matthew [1895a, Pl. II, fig. 7a], is an impression in the shale, the cardinal slopes of which have been broken away. The dorsal valve [Matthew, 1895a, Pl. II, fig. 7b] may be compared with the dorsal valve of *L. martinensis* [1895a, Pl. II, fig. 6d].

Matthew [1895a, p. 114] described the occurrence of the central and lateral scars in the ventral valve, but he does not show them in his figures, and I can not clearly see them in the type specimens received from him.

The specific name is derived from St. Martins, in which the type specimens were collected.

FORMATION AND LOCALITY.—Middle Cambrian: (2g and 2f)^a Sandstones of Division 1b1; (2h) sandstones of Division 1b2; and (2i) sandstones of Division 1b3; all in Matthew's [1895, p. 108] *Protolenus* zone on Hanford Brook, St. John County, New Brunswick.

LINGULELLA MINOR (Matthew).

Plate XXXVII, figures 3, 3a–g.

Lingulella starri minor MATTHEW, 1892, Trans. Roy. Soc. Canada for 1891, vol. 9, sec. 4, No. 5, pp. 58–59, Pl. XI, figs. 5a–b. (Described and discussed as below. It is a new variety, though not so described. The specimens represented by figs. 5a and 5b are redrawn in this monograph, Pl. XXXVII, figs. 3 and 3a, respectively.)

The original description by Matthew follows:

This neat little species is referred to *Lingulella starri* on account of the sculpture, though it is different both in form and size. It is only about two-thirds of the size of that species, and is more prolonged in front. The dorsal valve also is ovate, not oblately orbicular as in the type.

The sculpture consists of concentric ridges, which appear crenulated owing to the interrupted, faint, radiating ridges that traverse them. At intervals there are stronger concentric lines marking stages of growth. The ridges are not so sharply marked as in *L. starri*, and the shell is much thinner.

Length of ventral valve, 11 mm.; width, 9 mm. The dorsal valve is 1 mm. shorter.

Observations.—The types of *Lingulella starri* are in this monograph referred to *Lingulella* (*Lingulepis*), and the variety *minor* of Matthew [1892, p. 58] to *Lingulella* as a distinct species. During the summer of 1899 I visited the type locality on Long Island, and found this shell in the shales, and also a smaller shell that appears to be the young of *Lingulella minor*, in a fine, compact, shaly sandstone, and in lenticular masses of limestone interbedded in the shales. There is also great variation in outline and size of the shells in the siliceous shale.

FORMATION AND LOCALITY.—Upper Cambrian: (2x)^b Thin-bedded sandstones of Division 2 of Matthew, on the south shore of Long Island, Kennebecasis Bay [G. F. Matthew, 1898b, p. 38], St. John County, New Brunswick.

(3n) Thin-bedded sandstones on Salmon River, Gillis Hill, 13 miles (20.9 km.) south of Marion Bridge, eastern Cape Breton, Nova Scotia, Canada.

^a 2f is the type locality, though the specimens in the United States National Museum collections to which that number is assigned were collected later than the type specimens.

^b 2x is the type locality, though the specimens in the United States National Museum collections to which that number is assigned were collected later than the type specimens.

LINGULELLA MOSIA (Hall).

Plate XVIII, figures 1. 1a-f.

Lingula mosia HALL, 1863, Sixteenth Ann. Rept. New York State Cab. Nat. Hist., p. 126, Pl. VI, figs. 1-3a. (Described and discussed as a new species; see below.)

Lingula mosia HALL, 1867, Trans. Albany Inst., vol. 5, pp. 102-103, Pl. I, figs. 1-3a. (Copy of preceding reference.)

Lingula mosia Hall, SARDESON, 1896, Bull. Minnesota Acad. Nat. Sci., vol. 4, No. 1, pt. 1, p. 95. (Discussed from a new locality.)

The original description by Hall follows:

Shell small, subelliptical, or ovate-spatulate, little convex, concentrically striated. The slopes below the beak are sometimes nearly straight for a short distance, and often curving from the beak to the base. The specimens are for the most part impressions in sandstone, with little of the shell remaining, but the form is very distinct from any of the described species; and being limited in vertical range, and with a somewhat wide horizontal extension, it becomes of interest in its associations.

The study of a large number of specimens has added little to the knowledge of this species. Nearly all the shell structure has been removed, and only more or less imperfect casts remain in the sandstone. The outer surface is marked by fine concentric striæ and lines of growth, and in one cast there is an indication of irregular, almost inosculating striæ, such as occur on portions of the surface of *Obolus* (*Westonia*) *ella* (Hall and Whitfield). The few fragments of the shell in the material studied indicate that it was of medium thickness and formed of two or more layers, and that the inner lamellæ were marked by fine radiating striæ.

The average size of the ventral valve is about 8.5 mm. in length by 7 mm. in width. The dorsal valve is a little shorter in proportion to the width.

The area of the ventral valve is high; it is broken midway by a strong narrow pedicle groove, and on each side, well out toward the margin, by very narrow flexure lines. Strong striæ of growth cross the area parallel to its base. They arch transversely over the cast of the pedicle furrow. The area of the dorsal valve is well defined; it is crossed by fine striæ of growth, and marked by oblique flexure lines that outline a rather broad space between them.

The casts of the interior of the ventral valve show traces of the visceral cavity and main vascular sinuses, and the central and anterior lateral muscle scars have been seen in the dorsal valve.

Observations.—The broad, almost subquadrate outline of some of the specimens of the dorsal valve suggest *Obolus* (*Westonia*) *ella* (Hall and Whitfield) (Pl. XLVII) and there is a trace of the surface of the latter. A closer comparison of the two shows that *O.* (*W.*) *ella* is a broader shell, with a characteristic surface ornamentation. *Lingulella mosia* may be the Upper Cambrian representative of the Middle Cambrian *Obolus* (*Westonia*) *ella*.

FORMATION AND LOCALITY.—Lower Ordovician: (364a [Sardeson, 1896, p. 95]) reported by Sardeson from the Oneota dolomite along St. Croix River in both Wisconsin and Minnesota.

Upper Cambrian: (113) "St. Croix sandstone" at La Grange Mountain (or Barn Bluff), near Red Wing, Goodhue County, Minnesota.

(78 and 78s)^a "St. Croix sandstone," quarry near St. Croix River in suburbs of Osceola, Polk County; (85)^b "St. Croix sandstone" near *Prairie du Sac*, Sauk County; (85x and 85x) upper beds of the "St. Croix sandstone" near Mazomanie, Dane County; (99a) "St. Croix sandstone" near Pilot Knob, Adams County; (100) "St. Croix sandstone" near Menomonie, Dunn County; (79 and 79s) "St. Croix sandstone" near Hudson, St. Croix County; (98x) "St. Croix sandstone" near Eau Claire, Eau Claire County; (78b) "St. Croix sandstone" 50 feet (15.2 m.) above St. Croix River, near the landing at Osceola, Polk County; (98a) "St. Croix sandstone" at Marine Mills, Washington County; (86) "St. Croix sandstone," at Van Ness's quarry, Gibraltar Bluff, Lodi, Columbia County; and (85s) "St. Croix sandstone" at *Prairie du Sac*, Sauk County; all in Wisconsin.

(364) St. Lawrence formation of Sardeson [1896, p. 95], in both Wisconsin and Minnesota.

(341a) Sandstone at McGregor, Clayton County, Iowa.

^a The species also occurs in Locality 78e (p. 214).

^b 85 is the type locality, though the specimens in the United States National Museum collections to which that number is assigned were collected later than the type specimens.

LINGULELLA MOSIA OSCEOLA (Walcott).

Plate XVIII, figures 2, 2a-c.

Obolus (Lingulella) mosia osceola WALCOTT, 1898, Proc. U. S. Nat. Mus., vol. 21, p. 409. (Uncharacterized as below as a new variety.)

There is a considerable variation in the form of *Lingulella mosia* (Hall) as it occurs in the brown sandstone of Osceola, and for the narrow, more elongate variety the name *osceola* was proposed [Walcott, 1898b, p. 409]. It is an intermediate form between *L. mosia* and *L. perattenuata* (Whitfield) (Pl. XXI). The same, or a closely allied, variety occurs in a light-colored sandstone at Eau Claire.

The varietal name is derived from Osceola, the type locality.

FORMATION AND LOCALITY.—Upper Cambrian: (78 and 78s)^a “St. Croix sandstone” in quarry near St. Croix River, in suburbs of Osceola, Polk County, and (98) “St. Croix sandstone” near Eau Claire, Eau Claire County; both in Wisconsin.

LINGULELLA NANNO (Walcott).

Plate XXIV, figures 1, 1a-d.

Obolus (Lingulella) nanno WALCOTT, 1898, Proc. U. S. Nat. Mus., vol. 21, p. 409. (Described as below as a new species.)

Shell very small; general form elongate ovate, with the ventral valve subacuminate to acuminate, and the dorsal valve elongate in outline. The convexity of the two valves is moderate in the very small shells, increasing slightly with the increase in size. Average length of the ventral valve is about 2 mm., and that of the dorsal valve a little less.

The surface of the shell as it appears in the hard, fine-grained, drab-colored limestone is marked by fine, concentric striæ, and very faint traces of radiating striæ.

Observations.—This minute species occurs in thin layers of limestone interbedded in the Conasauga (“Coosa”) shale. Its small size and acuminate ventral valve distinguish it from other species. It is associated with *Dicellogmus appalachia* Walcott and fragments of trilobites.

FORMATION AND LOCALITY.—Middle Cambrian: (16) *Conasauga limestone*, Blountsville Valley, Blount County; and (91) *Conasauga* (“Coosa”) shale at Cedar Bluff, Cherokee County; both in Alabama.

LINGULELLA NATHORSTI Linnarsson.

Plate XXXI, figures 1, 1a-h.

Lingulella? nathorsti LINNARSSON, 1876, Bihang till K. svensk. Vet.-Akad. Handl., Bd. 3, No. 12, pp. 15-16, Pl. III, figs. 24-30. (Described and discussed in English as a new species.)

This is a medium-sized well-characterized species. As the illustrations of Linnarsson [1876, Pl. III] are not altogether satisfactory I have had several drawings made from material received from Dr. G. Lindström.

Plate XXXI, figures 1, 1a-b, represents specimens from the gray, arenaceous, shaly sandstones at Andrarum, and Plate XXXI, figures 1c-e, specimens from the hard, dark-gray sandstones in Dalarne. Specimens from the dark sandstone show the surface of the shell to have been marked by concentric striæ and lines of growth and very fine radiating striæ. The casts from the arenaceous shales show the area of the valves (Pl. XXXI, figs. 1 and 1b) and traces of the vascular markings.

Observations.—In form and outline *Lingulella nathorsti* may be compared with *L. radula* Matthew, but it differs greatly from that species in its surface characters.

The specific name was given in honor of Mr. A. G. Nathorst.

FORMATION AND LOCALITY.—Lower Cambrian: (320x) *In strata with Holmia kjerulfi* at Andrarum, 20 miles (32 km.) northwest of Simrishamn, Province of Christianstad; and (8y) with *Torellella ævigata* in the “Sparagmite” sandstone, at Skårösen, northwest Dalarne, Province of Kopparberg; both in Sweden.

^a78 is the type locality.

LINGULELLA NICHOLSONI Callaway.

Plate XXX, figures 3, 3a-f.

Lingulella nicholsoni CALLAWAY, 1874, Quart. Jour. Geol. Soc. London, vol. 30, p. 196. (Name proposed.)*Lingulella nicholsoni* CALLAWAY, 1877, idem, vol. 33, pp. 668-669, Pl. XXIV, figs. 11, 11a-b. (Described and discussed as below. Figs. 11 and 11b are reproduced in this monograph, Pl. XXX, figs. 3 and 3a, respectively.)*Lingulella nicholsoni* CALLAWAY, DAVINSON, 1883, British Fossil Brachiopoda, vol. 5, pt. 2, pp. 208-209, Pl. XVII, figs. 31, 31a, and 32. (The discussion of the species, the localities, and the figures given in the preceding reference are here copied.)*Lingulella nicholsoni* Callaway?, MATLEY, 1902, Quart. Jour. Geol. Soc. London, vol. 58, pt. 1, p. 141. (A new locality mentioned.)

The original description by Callaway follows:

Ovate, depressed, widest about the middle, two-thirds as broad as long, front and sides rounded, beak moderately acuminate, area of ventral valve striated, the striae parallel to the external slope of the valve, pedicle groove divided by a narrow ridge down the middle; visceral surface pitted; exterior surface marked by fine concentric lines of growth. Length, 5 lines; width, 3.5 lines.

This is a larger shell than *Lingulella ferruginea* Salter and its sides are not so parallel. It closely resembles *L. lepis* (Salter); but *L. lepis* is wider toward the front, according to Davidson's figures [1883, Pl. XVII, figs. 31, 31a, and 32].

In a collection kindly lent to me by Dr. Charles Lapworth I found this species to vary greatly in outline in the shales. It is a well-marked species. Plate XXX, figures 3b and 3c, shows probably the most characteristic adult forms.

The specific name was given in honor of Mr. Nicholson.

FORMATION AND LOCALITY.—Upper Cambrian: (304i [Callaway, 1877, p. 669]) *Shinerton shales at Shinerton, Mary Dingle, Dryton, Cressage, 1 mile (1.6 km.) west of Cressage, west of Harley, and under, Cound-Moor quarry*; and (304k [Davidson, 1883, pp. 208 and 209]) *Shinerton shales at Bull Hill Cottage and Pewardine*; all in South Shropshire, England.

(3041) In the collection received from Dr. Charles Lapworth, collected by R. R. Rhodes, of the Geological Survey of Great Britain, the species is recorded in shales at the following localities: 2246, 2481, 2499, 2512, 2513, 2541, 2548, 2556, 2567, 2625, and 2627, all on Shinerton Brook and vicinity, South Shropshire, England.

(304a [Groom, 1902, p. 110]) "Bronsil shales;" and (304b [Groom, 1902, p. 109]) lower part of the "White Leaved Oak shales" (the zone of *Polyphyra*); both in the Malvern Hills, between Herefordshire and Worcestershire, England.

LINGULELLA ORA (Walcott).

Plate XXXV, figures 9, 9a-d.

Obolus (Lingulella) orus WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 330. (Characterized as below as a new species.)

This is a shell of the *Lingulella manticula* (White) form, but differs from it in being more elongate; ventral valve more acuminate and dorsal valve proportionately larger. Its nearest allies in form are among the group of narrow, elongate shells occurring in New Brunswick and Cape Breton. It differs from all of them—*Lingulella collicia* (Matthew), *L. flumenis* (Matthew), *L. cania* (Walcott), etc.—in having a thick, strong shell and usually more acuminate dorsal valve. The exterior surface bears rather strong concentric lines of growth and very fine, irregular, undulating, elevated striae that suggest the surface of *Obolus (Westonia) ella* (Hall and Whitfield) when seen in reflected light with a strong magnifier.

This little shell occurs abundantly, but good interiors have not been found. The main vascular sinuses appear to be submarginal in both valves, and the visceral area of the dorsal valve narrow, extending a little beyond the center of the valve.

FORMATION AND LOCALITY.—Upper Cambrian: (9p) *About 160 feet (48.8 m.) above the porphyry contact in the limestones of the Reagan sandstone, in SE. ¼ NE. ¼ sec. 2, T. 4 N., R. 13 W.*; and (9q) *about 10 feet (3 m.) above the porphyry contact and 90 feet (27.4 m.) below the Arbuckle limestone, in limestones of the Reagan sandstone, in middle of west half of sec. 2, T. 4 N., R. 13 W.*; both about 15 miles (24.2 km.) northwest of Fort Sill, Comanche County, Oklahoma.

A single specimen of a ventral valve 4 mm. in length that is much like the corresponding valve of *Lingulella ora* occurs at the following locality. More and better material is needed before an identification can be made that is more than tentative.

Middle Cambrian: (11m) Drill cores of limestone in the Bonnetterre limestone at horizons 10 and 20 feet (3 and 6 m.) above the Lamotte sandstone at Flat River, St. Francois County, Missouri.

LINGULELLA OWENI (Walcott).

Plate XVIII, figures 5, 5a-f.

Obolus (Lingulella) oweni WALCOTT, 1898, Proc. U. S. Nat. Mus., vol. 21, p. 410. (Described and discussed essentially as below as a new species.)

General form ovate, with the ventral valve obtusely acuminate, and the dorsal valve more broadly rounded posteriorly; valves appear to have been moderately convex, as far as can be determined from the flattened specimen in the shaly sandstones. Surface of shell marked by concentric lines and striæ of growth and indistinct, radiating striæ. There are no traces of the interior markings observed. The shell is of medium thickness; none of the specimens show how it was built up, farther than that there were oblique lamellæ attached to the outer layer in the anterior portion of the valve. The largest ventral valve from Gibraltar Bluff has a length of 16.5 mm.; width, about 12 mm.; an associated dorsal valve 14 mm. in length, has a width of 11 mm. as it occurs flattened on the surface of the sandstone. A smaller shell referred to this species from Osceola averages from 6 to 8 mm. in length.

As shown in the cast of an interior of a shell, the area is rather long, and divided midway by a sharp pedicle furrow; the flexure lines are situated about midway between the cast of the pedicle furrow and the lateral margin. The area formed a thin shelf between the pedicle groove and the lateral margins, the undercut extending far back under the area; a broken portion of this is preserved on the cast illustrated by figure 5a.

One cast of the interior of a ventral valve shows a slight trace of the visceral area (Pl. XVIII, fig. 5d). In a cast of a dorsal valve (fig. 5b) both the central and anterior lateral muscle scars are somewhat indistinctly preserved.

Observations.—This species is most nearly related to *Lingulella ampla* (Owen). It differs, as far as can be determined from the material for comparison, in being less elongate and in the position of the central and anterior lateral muscle scars in the dorsal valve, as may be seen by comparing Plate XVIII, figure 5b, with Plate XXVIII, figure 1g. The typical form of this species is represented on Plate XVIII, figures 5, 5b, and 5c, and a smaller form, which has been referred to it, by figures 5d, 5e, and 5f.

The species differs strongly from *Obolus (Westonia) stoneanus* (Whitfield) in its surface markings, although the outline of the valves is almost the same in the two species.

The specific name was given in honor of Dr. D. D. Owen.

FORMATION AND LOCALITY.—**Upper Cambrian:** (78c) "St. Croix sandstone" at Osceola, Polk County; (86) "St. Croix sandstone" at Van Ness's quarry, Gibraltar Bluff, Lodi, Columbia County; (85z) "St. Croix sandstone" at Madison, Dane County; (85a) "St. Croix sandstone" at Brown's quarry, Prairie du Sac, Sauk County; and (85s) "St. Croix sandstone" at Prairie du Sac, Sauk County; all in Wisconsin.

(97) "St. Croix sandstone" at Reads Landing, foot of Lake Pepin, Wabasha County, Minnesota.

LINGULELLA PERATTENUATA (Whitfield).

Plate XXI, figures 1, 1a-i.

Lingulepis perattenuatus WHITFIELD, 1877, U. S. Geog. and Geol. Survey Rocky Mtn. Region, Rept. Geol. Black Hills of Dakota, Prelim. Rept., p. 9. (Described and discussed as on p. 524 as a new species.)

Lingulepis perattenuatus WHITFIELD, 1880, U. S. Geog. and Geol. Survey Rocky Mtn. Region, Rept. Geol. and Resources Black Hills of Dakota, by Newton and Jenney, p. 337, Pl. II, figs. 7-9. (Copy of preceding reference. The specimens represented by figures 7, 8, and 9 are redrawn in this monograph, Pl. XXI, figs. 1i, 1h, and 1b, respectively.)

Lingulepis cuneolus SCHUCHERT (in part) [not WHITFIELD], 1897, Bull. U. S. Geol. Survey No. 87, p. 259. (Merely refers Whitfield's *Lingulepis perattenuatus* to *L. cuneolus*.)

Obolus (*Lingulella*) *perattenuatus* (Whitfield), WALCOTT, 1899, Mon. U. S. Geol. Survey, vol. 32, pt. 2, p. 443. (Merely changes generic reference.)

The original description by Whitfield follows:

Shell spatulate or elongate-ovate, becoming acutely pointed toward the beak; sides below the middle of the length of the ventral valve rounded; front margin very regularly curved; cardinal slopes straight, or sometimes slightly convex; greatest width a little more than half the length of the ventral valve and sometimes nearly two-thirds as great. Surface of the ventral valve depressed convex, very slightly subangular along the middle above the lower third of the length, and a little more distinctly so in the upper part. Apex scarcely truncate. Dorsal valve considerably shorter than the ventral, broadly truncated at the upper end, the line of truncation being distinctly arched. Surface evenly convex. Structure of the surface of the shell polished, with fine, somewhat lamellose lines of growth.

The material studied by Whitfield, now in the collections of the United States National Museum, has been carefully worked over and the cardinal area of both valves developed in the casts of the interior of the shell (Pl. XXI, figs. 1 and 1d). The plane of the area of the ventral valve coincides near its edges with the edge of the shell, but it rises quite rapidly toward the pedicle furrow. It is divided at the center by a rather deep, strongly marked pedicle furrow and near the lateral margin by a rather sharp, very narrow flexure line (Pl. XXI, figs. 1a and 1c). The striæ of growth cross the area parallel with its base. They are sharp and crowded on the lateral slopes, but are very indistinctly preserved in the pedicle groove. The area of the dorsal valve is lower than that of the ventral and, in the typical specimens, shows nothing more than the fine striæ of growth (Pl. XXI, fig. 1i).

No traces of muscle scars or vascular markings have been found in the material from the type locality in the Black Hills, but, in some casts of the interiors of valves from Texas, traces of the visceral cavity and muscle scars are shown. In Plate XXI, figure 1e, the outline of the visceral cavity (ν) is preserved, also the main vascular sinus (νs).

Both valves of the shell are much thinner than in *Lingulella acutangula* (Roemer). The shell is formed of a thin outer layer and one or two inner layers or lamellæ, which occur in the posterior half of the shell. The surface of the outer layer is marked by concentric striæ and lines of growth and very fine, more or less interrupted radiating striæ. The inner layer is characterized on its outer surface by fine, concentric, radiating striæ. A few minute punctæ occur on the inner surface of several shells, as shown by the papillæ on the cast.

Observations.—The most nearly related species in the American Cambrian rocks is *L. acutangula* (Roemer). It differs in having a much thinner shell, and, as far as they are preserved, in the character and position of the interior markings and muscle scars.

The type species was described from the "Potsdam formation" of the Black Hills. From a recent study of the Black Hills Cambrian section I have found that it is from the Middle Cambrian sandstones and limestones as they occur near the headwaters of Red Canyon Creek and in the vicinity of Deadwood. It is also identified from the Middle Cambrian of central Texas and in the same fauna from the "Tonto" sandstone of the Grand Canyon of the Colorado, Arizona. In the Black Hills it is associated with *Lingulella* (*Lingulepis*) *acuminata* (Conrad) and *Dicellomus politus* (Hall).

FORMATION AND LOCALITY.—**Upper Cambrian:** (67c) Sandstone on Tatur Hill, 7 miles (11.2 km.) northwest of Burnet, Burnet County; (70) limestone near Morgans Creek, Burnet County; and (68y) interbedded sandstone and limestone on Packsaddle Mountain, Llano County; all in Texas.

Middle Cambrian: (355) Sandstones on Red Canyon Creek, southwest side of Black Hills; and (355f) sandstones near Deadwood, Black Hills; both in South Dakota.

(74) Sandstone about 300 feet (91.4 m.) above the base of the Tonto group, at the head of Nunkowep Valley; and (74d) sandstone beds in the "Tonto" shale just above massive sandstones near the mouth of Bass Canyon, on the south side of the Grand Canyon of the Colorado, southeast of Powells Plateau; both in the Grand Canyon of the Colorado, Arizona.

A single ventral valve of this species, or a closely related form, occurs in the following locality:

Middle Cambrian: (90) Siliceous limestone about 15 feet (4.6 m.) above the Coronado quartzite [Lindgren, 1905, p. 3], 0.5 mile (0.8 km.) southwest of Milk ranch, on the first spur north of the one which the main road follows, Clifton quadrangle (U. S. Geol. Survey), Graham County, Arizona.

LINGULELLA PHAON (Walcott).

Plate XXVI, figures 1, 1a-e.

Obolus (Lingulella) phaon WALCOTT, 1898, Proc. U. S. Nat. Mus., vol. 21, pp. 410-411. (Described and discussed essentially as below as a new species.)

General form ovate, with the ventral valve subacuminate, and the dorsal broadly ovate; valves of moderate convexity. Surface of the shell marked by fine concentric lines and striæ of growth, and very fine more or less interrupted radiating striæ; when the outer layer is exfoliated the inner surface is marked by numerous fine radiating striæ; the interior surface as seen in casts is more or less marked by rather large papillæ arranged in concentric lines, the papillæ corresponding to the pits or punctæ on the inner surface of the shell. The shell is rather thick, and is built up of a thin outer layer and several inner layers or lamellæ, the lamellæ toward the front being oblique to the outer layer. A large ventral valve 15 mm. in length has a width of 13 mm.; a dorsal valve 11 mm. long has a width of 10 mm.

As shown in the cast of the interior of the shell, the area of the ventral valve rises gradually from the margin toward the pedicle groove. It is broken midway by the cast of a strong pedicle furrow and a little more than halfway up toward the lateral margin by a strong flexure line; the striæ of growth are very fine and cross the area parallel with its base. The cast of the undercut shows that the area formed a thin shelf between the pedicle groove and the lateral margins. The area of the dorsal valve is well defined. As in the ventral valve the area formed a thin shelf, as shown by the cast of the undercut extending well over the area in several of the specimens; the cast of the broken edges of the undercut between the areas is shown by Plate XXVI, figures 1b, 1c, 1d.

The cast of the interior of the ventral valve (Pl. XXVI, figs. 1b and 1c) shows the strongly defined, narrow, visceral area (v), the trapezoidal area (c) in which the central, middle, and outside lateral muscle scars occur, also the anterior lateral muscle scars (j), and unusually strong main vascular sinuses (vs). In a specimen which is not illustrated, apparent lines of growth occur on the ridge in front of the trapezoidal area (c), a feature that is present in *L. hayesi* (Walcott) and *Obolus matinalis* (Hall). In a dorsal valve the relatively narrow central vascular area extends forward nearly to the center of the shell (Pl. XXVI, fig. 1d); central (h) and anterior lateral (j) scars are faintly indicated, also transmedian (i) scars, and the median septum (s); the main vascular sinuses (vs) are unusually deep and well defined.

Observations.—This species at first inspection might be taken for *Lingulella ampla* (Owen) (Pl. XXVIII). It occurs at the same horizon in association with *Dicellomus politus* (Hall). It differs in having a broader and less elongate shell, with the visceral area of the dorsal valve terminating near the center instead of forward of the center, and, as far as can be determined from the material at hand, in having a thicker shell. It also averages about one-fourth less in size.

FORMATION AND LOCALITY.—Upper Cambrian: (98 and 98x)^a "St. Croix sandstone" near Eau Claire, Eau Claire County; and (82a) "St. Croix sandstone" 25 feet (7.6 m.) above the water level near the Knapp, Stout and Company's buildings, Menomonie, Dunn County; both in Wisconsin.

(84a) "St. Croix sandstone" at River Junction, Houston County, 20 miles (32.2 km.) below Dresbach, Minnesota.

LINGULELLA POGONIPENSIS (Walcott).

Plate XX, figures 3, 3a-c.

Obolus (Lingulella) pogonipensis WALCOTT, 1898, Proc. U. S. Nat. Mus., vol. 21, pp. 411-412. (Described and discussed as below as a new species.)

Shell rather large, general form ovate, almost ovate cuneate in the ventral valve; dorsal valve more ovate. Valves moderately convex. Surface of the shell marked by numerous concentric lines and striæ of growth, and very fine radiating striæ; the finer concentric striæ are slightly irregular, but not nearly so much so as in many species of the genus. The outer

^a 98x is the type locality.

surface of the inner layer is marked by very fine radiating striæ, also concentric lines of growth. The shell is below the average thickness and is formed of a thin outer layer and one or more inner layers or lamellæ.

The largest ventral valve has a length of 15 mm.; width, 11 mm. As shown by a partial cast the area is of medium length, and divided midway by a narrow, strongly marked cast of the pedicle furrow.

Observations.—In form the valves of this species somewhat resemble those of *Lingulella ampla* (Owen) (Pl. XXVIII), and more closely those of *L. isse* (Walcott) (Pl. XXXIX). In the absence of all interior markings no further comparisons can be made.

The species derives its specific name from its occurrence in the Pogonip limestone.

FORMATION AND LOCALITY.—Passage beds between the Upper Cambrian and the Ordovician: (201) *Arenaceous Pogonip limestone, on east slope of ridge east of Hamburg Ridge*; (205) siliceous limestone on Roundtop Mountain; (203a) limestones at base of Pogonip limestone, in the spur on Hamburg Ridge extending out southwest from Wood Cone; and (211) siliceous Pogonip limestone, on spur of Hamburg Ridge extending southwest from Wood Cone; all in the Eureka district [Hague, 1892, Atlas], Eureka County, Nevada.

Specimens somewhat doubtfully referred to this species occur at the following localities:

Upper Cambrian: (32f) Thin-bedded siliceous limestones near the top of the Upper Cambrian, about 2 miles (3.2 km.) southeast of Muskrat Spring, on the northwest face of Grantsville Peak, Stansbury Range, Tooele County, Utah.

Upper? Cambrian: (358a) Siliceous limestone in Pinal County, Arizona.

LINGULELLA PRIMA (Conrad MS.) (Hall).

Plate XXVII, figures 1, 1a-c.

Lingula ovata EMMONS [not McCoy], 1842, Nat. Hist. New York, Geology, pt. 2, p. 105. (Mentioned.)

Lingula prima (CONRAD MS.) HALL, 1847, Nat. Hist. New York, Paleontology, vol. 1, p. 3, Pl. I, fig. 2. (Described and discussed. It is the first description of the fossil, though no reference is made to the fact that it is a new species.)

Lingula prima Hall, EMMONS, 1855, American Geology, vol. 1, pt. 2, p. 202. (Described.)

Lingulepis prima (Hall), MILLER, 1877, American Paleozoic Fossils, Catalogue, p. 115. (Merely changes generic reference.)

Obolella prima (Hall), WHITFIELD, 1884, Bull. Am. Mus. Nat. Hist., vol. 1, No. 5, pp. 142-143, Pl. XIV, figs. 3-5. (Discussed.)

Lingulella? prima (Hall), HALL and CLARKE, 1892, Nat. Hist. New York, Paleontology, vol. 8, pt. 1, p. 69, footnote. (Discussed.)

Lingulepis prima (Hall), SCHUCHERT (in part), 1897, Bull. U. S. Geol. Survey No. 87, p. 260. (Merely changes generic reference. Includes species other than Hall's "*Lingula prima*.")

Obolus (Lingulepis) primus (Hall), WALCOTT, 1901, Proc. U. S. Nat. Mus., vol. 23, p. 673. (Merely changes generic reference.)

General form subovate with the ventral valve subacuminate and the dorsal valve broadly subacuminate. There is a tendency in some individuals to a subcuneate outline. Valves moderately convex, increasing in some shells to almost strongly convex. There is some range of variation in the outlines of the valves, as shown by Plate XXVII, figures 1 and 1a. The surface of the shell is marked by concentric lines and small undulations of growth and by very fine radiating striæ. When the outer layer is exfoliated the inner layer is seen to be marked by sharp radiating striæ and a few concentric lines of growth. The interior surface shows fine radiating striæ and a few scattered pits. The shell is of medium thickness and formed of a thin outer layer and several inner layers, or lamellæ, which are more or less oblique to the outer layer; the lamellæ are much more numerous toward the margins and form a rather thick rim around the anterior and anterolateral margins. The average length of the ventral valve is 5 mm., width 4 mm. The dorsal valve is slightly shorter in proportion to its width.

As shown in the interior casts the area of the ventral valve is relatively short; it is divided at the center by a rather strongly marked pedicle furrow and well out toward its margins by clearly defined flexure lines. Faint traces of striæ of growth cross the area parallel with its base; the area of the dorsal is not shown in any of the specimens in the collection.

The cast of the interior of the ventral valve shows the visceral cavity (v), the trapezoidal area (c), and the rather strong median ridge, which extends from the area forward to the anterior

margin of the visceral area. This ridge corresponds to a median groove passing anteriorly into the heart-shaped cavity. There are no clearly defined muscle scars in any specimen in the collection, although the trapezoidal area in the ventral valve, in which the central, middle, and outside lateral muscle scars usually occur, is fairly well preserved in one specimen. None of the casts of the dorsal valve show more than the cast of the median ridge or septum. Of the markings left on the shell by the vascular system only the main vascular sinuses have been preserved on the cast of the ventral valve.

Observations.—This is a small but striking species that occurs in the sandstones east of the Adirondack Mountains. In outline and form it may be grouped with *Lingulella ferruginea* Salter and *L. bellula* (Walcott) (Pl. XIX). It is a larger and more acuminate shell than *L. ferruginea*, and its dorsal valve is distinguished from that of *L. bellula* by being shorter and broader anteriorly. It occurs quite abundantly in the thin beds of hard sandstones at Ausable Chasm, below Keeseville, Essex County, New York, associated with *Ptychoparia minuta* and *L. (Lingulepis) acuminata* (Conrad)(?). The interior of the ventral valve resembles typical forms of *Obolus* more nearly than the typical forms of *Lingulella*. This may be due to the state of preservation or it may be that, despite the *Lingula*-like outlines of the valves, it is more a true *Obolus* in its interior markings as these are developed in *O. matinalis* (Hall). (Compare Pl. VIII, fig. 1e, with Pl. XXVII, fig. 1.)

Whitfield [1884, p. 142] referred the species to the genus *Obolella*. There is a strong resemblance between the dorsal valve of the species and that of some of the species of *Obolella*, but a careful study of a large amount of material shows that this resemblance is confined to the dorsal valve. He also refers "*Obolella nitida*" Ford to this species, but "*O. nitida*" is a true *Acrotreta* and occurs in the lower portion of the *Olenellus* fauna of the Lower Cambrian, and *Lingulella prima* (Hall) is from the Upper Cambrian.

Dwight [1886, p. 208] mentions "*Obolella (Lingulella) prima*" as occurring in "Potsdam" strata at Poughkeepsie, New York, but inasmuch as he does not describe the specimen, and the form has not been found in other extensive collections that have been made there, the reference is considered as exceedingly doubtful. I think Dwight had small specimens of the dorsal valve of *Lingulella (Lingulepis) acuminata* (Conrad), which occurs at the locality at Poughkeepsie.

FORMATION AND LOCALITY.—Upper Cambrian: (77)^a Sandstone near the water below the falls at the high bridge, and also at several horizons in the section, the highest point being 70 to 75 feet (21 to 23 m.) above the water, in Ausable Chasm; (367f) sandstone at French Creek, 1 mile (1.6 km.) east of Keeseville; (367g) sandstone in the bed of the brook, in the suburbs of Port Henry; (367h) Rosses Bridge, 4 miles (6.4 km.) west of Essex; (136) Potsdam sandstone in bank of stream opposite the first switch on the Port Henry and Maine Railroad out of Port Henry; and (338t) Potsdam sandstone in Ausable Chasm, below Keeseville; all in Essex County, New York.

LINGULELLA? PRIMÆVA Hicks.

Plate XXXI, figures 5, 5a.

Lingulella primæva HICKS, 1871, Quart. Jour. Geol. Soc. London, vol. 27, p. 401, Pl. XV, figs. 13 and 14. (Described as a new species.)

Lingulella primæva HICKS, SALTER and ETHERIDGE, 1881, Mem. Geol. Survey Great Britain, vol. 3, 2d ed., p. 538. (Localities mentioned.)

Lingulella primæva HICKS, 1881, Popular Science Review, new ser., vol. 5, p. 297. (Mentioned only.)

Lingulella primæva HICKS, DAVIDSON, 1883, British Fossil Brachiopoda, vol. 5, pt. 2, p. 208, Pl. XVII, figs. 33 and 34. (Described and discussed. Fig. 33 is drawn from the specimen figured by Hicks, 1871, Pl. XV, fig. 14. Figs. 33 and 34 are reproduced in this monograph, Pl. XXXI, figs. 5a and 5, respectively.)

This species is rather doubtful, owing to its condition of preservation, which renders it quite difficult to make any comparison with other described species. It occurs in association with *L. ferruginea* Salter, but is a much larger species.

FORMATION AND LOCALITY.—Middle? Cambrian: (366c) "*Caerfai group*" [Salter and Etheridge, 1881, p. 538] at *Caerfai*, *Nuns Hill*, and *Porthclais Harbor*, all south of *St. Davids*; and (318i) red shales of the *Caerfai group* at *St. Davids*; both in South Wales.

^a77 is the type locality, though the specimens in the United States National Museum collections to which that number is assigned were collected later than the type specimens.

LINGULELLA PUNCTATA (Walcott).

Plate XX, figures 6, 6a.

Lingula? mantieula WALCOTT [not WHITE], 1884, Mon. U. S. Geol. Survey, vol. 8, pp. 13-14, Pl. IX, fig. 3, and Pl. XI, fig. 2. (Discussed. The specimens represented by Pl. IX, fig. 3, and Pl. XI, fig. 2, are redrawn in this monograph, Pl. XX, figs. 6 and 6a, respectively.)

Obolus (Lingulella) punctatus WALCOTT, 1898, Proc. U. S. Nat. Mus., vol. 21, pp. 412-413. (Described as below as a new species.)

General form ovate, with the ventral valve subacuminate. Valves moderately convex, with the dorsal valve having a slightly depressed median sinus that extends from near the umbo to the anterior margin. Surface of shell marked by lines and striæ of growth, and very fine, slightly undulating striæ; also a few faintly indicated radiating striæ; when the outer layer is exfoliated the outer surface of the inner layer is seen to be marked by numerous and very fine radiating striæ, in addition to the concentric lines of growth; the interior of the shell, as shown by the casts, was strongly pitted or punctate, the punctæ being arranged in concentric lines following the lines of growth. The shell is relatively thin and formed of a thin outer layer and one or more thin inner layers or lamellæ.

The type specimen of the ventral valve has a length of 9 mm., width 6.5 mm. An associated dorsal valve has a length of 7 mm., width 5.5 mm.

The only interior that shows anything more than the punctate surface is that of the dorsal valve. In this the area is partly shown; it is relatively short and marked by fine striæ parallel to its base, and two imperfectly developed flexure lines. The cast of a narrow median septum is well shown, and on each side of it the middle lateral muscle scars. The path of advance of the central muscle scars is quite plain, also one of the scars. The only trace of the vascular system is a portion of a main vascular sinus.

This form owes its specific name to the concentrically punctate interior of the shell.

FORMATION AND LOCALITY.—Upper Cambrian: (3*f*) Limestone at summit of canyon, 10 miles (16.1 km.) south of Egan Canyon, east side of Egan Range, White Pine County; (8*o*) limestone on the slope of the ridge where the range swings around to the northwest, 2 miles (3.2 km.) north of Aurum, Schell Creek Range, White Pine County; (6*l*) limestone in the Dunderberg shale [Walcott, 1908*f*, p. 184], a little south of the Hamburg mine, Eureka district [Hague, 1892, Atlas], Eureka County; and (3*z*) limestone in the Dunderberg shale [Walcott, 1908*f*, p. 184], in canyon immediately north of Adams Hill, Eureka district [Hague, 1892, Atlas], Eureka County; all in Nevada.

Middle Cambrian: (7*i*) Limestone just west of the summit on the road east of Schellbourne, Schell Creek Range, White Pine County, Nevada.

(54) Eldorado limestone [Walcott, 1908*f*, p. 184], on east slope of Prospect Mountain, in New York Canyon; (57) shaly limestone in the Eldorado limestone [Walcott, 1908*f*, p. 184], at the 700-foot (213.4 m.) level in the Richmond mine, Ruby Hill [Hague, 1892, p. 43, and Pl. I, opposite p. 116]; and (58) shaly limestone in upper beds of Secret Canyon shale, east side of New York and Secret canyons; all in the Eureka district [Hague, 1892, Atlas], Eureka County, Nevada.

LINGULELLA QUADRILATERALIS (Walcott).

Plate XXXIX, figures 6, 6a.

Obolus (Lingulella) quadrilateralis WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 331. (Described and discussed as below as a new species.)

General form rounded, quadrilateral; valves moderately convex. Surface marked by concentric lines and ridges of growth with fine striæ between. The surface of the inner layers of the shell is shiny and marked by fine radiating striæ in addition to the concentric lines. The shell is rather thin; it is built up of several layers.

Observations.—This species differs from other described species by its subquadrilateral outline. In this respect it may be compared with *Obolus (Westonia) chuarensis* (Walcott) (Pl. XXV), from which it differs in having a thinner shell and different surface markings.

FORMATION AND LOCALITY.—Middle Cambrian: (91) *Conasauga* ("Coosa") shale, at Cedar Bluff, Cherokee County; and (56*q*) limestone at the very top of the *Conasauga* limestone, in quarry at Ketonah, about 5 miles (8 km.) northeast of Birmingham, Jefferson County; both in Alabama.

(140a) Shales 200 yards (182.9 m.) east of Thomas Mills, 5 miles (8 km.) north of Cave Spring, Floyd County, Georgia.

LINGULELLA RADULA Matthew.

Plate XLV, figures 1, 1a-1.

Lingulella radula MATTHEW, 1891, Trans. Roy. Soc. Canada, 1st ser., vol. 8, sec. 4, No. 6, pp. 147-148, Pl. XV, figs. 7a-b and 8a-e. (Described and discussed as a new species. Pl. XLV, figs. 1, 1a, 1b, 1c, and 1e, are drawn from specimens in Matthew's type material, but further identification is impossible.)

Lingulella radula aspera MATTHEW, 1903, Geol. Survey Canada, Rept. Cambrian Rocks Cape Breton, pp. 204-205, Pl. XV, figs. 2a-d. (Described and discussed as a new variety.)

General form ovate cuneate, with the ventral valve subacuminate and the dorsal valve broadly ovate in outline; valves apparently moderately convex, but this is uncertain, as the shells have all been compressed in the arenaceous shale. Surface marked by concentric lines of growth and very fine, irregular striæ. It is the type of surface of *Obolus* (*Westonia*) *ella* (Hall and Whitfield) or *Lingulella* (*Lingulepis*) *gregwa* (Matthew), reduced so that the surface, under a strong magnifier, has a roughened or minutely papillose appearance. Matthew [1891, p. 148] describes it as due to wavy squamose ridgelets having the edges and points directed forward, as in *Botsfordia pulchra* (Matthew). Owing to this roughened surface the outer layer of the shell usually adheres to the matrix, leaving the dark, shiny surface of the inner layer. The inner surface is marked by concentric rows of punctæ and fine radiating striæ. The shell is of medium thickness and formed of a thin outer layer and several inner layers or lamellæ, which are more or less oblique to the outer layer on the anterior half of the shell. One of the largest ventral valves has a length of 10 mm., width 8 mm.; a large dorsal valve has a length of 9 mm., width 8 mm.

The cardinal area and pedicle groove are usually obscured by the adhering fragments of shell. The pedicle groove is strong and narrows gradually as it crosses the long area of the ventral valve. The area of the dorsal valve is short and broad.

The cast of the visceral cavity (v) is preserved in a number of specimens. In Plate XLV, figures 1 and 1i, the heart-shaped pit (x), so characteristic of *Obolus* and of *Lingulella acutangula* (Roemer), is clearly outlined. A narrow median septum (s) is found in the dorsal valve (Pl. XLV, figs. 1j and 1l), and the anterior lateral muscle scars (j, fig. 1i) are clearly shown in the ventral valve. The centrals, middle laterals, and outside laterals can not be differentiated in the trapezoidal area (c) in front of the heart-shaped pit. On the dorsal valve the centrals (h, figs. 1d, 1j, and 1l) and anterior laterals (j, fig. 1j) are finely preserved.

Considerable portions of the markings of the vascular system are preserved on the casts of the interior of the valves. The main vascular trunks of the ventral valve are shown by figures 1, 1a, and 1c, and the position of the parietal scar is also seen at ps (figs. 1a, 1c, and 1i).

Observations.—Doctor Matthew sent me the types of this species for study and illustration. I have not been able to interpret some of the interior markings in the manner that his figures indicate, but this is not unexpected when the obscure character of most of the specimens is considered. When at St. John, in 1877, I collected a large number of specimens of this species, and, as they are somewhat better preserved than the types, drawings have been made of the casts of the interiors of three ventral valves and one dorsal valve.

The variety, spoken of by Matthew [1903, p. 204], from the lower portion of Division 2c shows the outer surface unusually well preserved, but I do not think it is a distinct species or worthy of a varietal name. In the collections made by Loper on McPhees Brook, Division 2 of Matthew's section, there are small specimens that correspond to Matthew's variety *aspera* collected on McNeil Brook; also adult specimens. The horizon is much lower, according to Matthew's sections, but the specimens are very much alike from the two localities.

FORMATION AND LOCALITY.—Middle Cambrian: (301y) *Shaly sandstones of Division C2c of Matthew, east side of Courtney Bay, St. John;* and (301x) sandstones of Division C2c of Matthew, in the city of St. John; both [Matthew, 1891, p. 148] in New Brunswick.

(307c [Matthew, 1903, p. 205]) Sandstones probably belonging with Division C2c of Matthew, on Mira River; and (307b) sandstone on McPhees Brook; both in eastern Cape Breton, Nova Scotia, Canada.

LINGULELLA RANDOMENSIS (Walcott).

Plate XXI, figures 5, 5a.

Obolus (Lingulella) randomensis WALCOTT, 1901, Proc. U. S. Nat. Mus., vol. 23, pp. 688-689. (Described and discussed as below as a new species.)

General form elongate ovate; ventral valve rather broadly subacuminate, and the dorsal valve slightly acuminate. The widest portion of the valves is the anterior third, from which they very gradually narrow toward the cardinal slopes. The convexity of the valves is moderate and uniform and nearly the same in each. Surface of the shell marked by fine concentric striae, and rather strong lines of growth, also fine radiating striae. The shell is formed of a few thin lamellae or layers, as far as can be determined from the fragments preserved on the casts in the sandstone. The longest ventral valve in the collection has a length of 10 mm. with a maximum width of 6 mm. The dorsal valve is slightly shorter.

As shown by the interior cast the area of the ventral valve is rather long, and extends well forward on the cardinal slopes. It is divided at the center by a narrow pedicle furrow and midway by a very slight flexure line. The base of the area curves backward over the margin, arching slightly forward before reaching a rather deep indentation at the center. The striae of growth cross the area parallel to its base. They are very sharp and fine and quite uniformly distributed over the area. Area of the dorsal valve unknown.

Observations.—This pretty species occurs in great numbers in thin layers of brown sandstone embedded in a dark shale a short distance below the *Olenus* zone. In form it resembles *Lingulella mosia osceola* (Walcott) (Pl. XVIII, figs. 2 and 2c). It differs from it in having a narrower pedicle furrow and, when comparing a large number of specimens, in being slightly more elongate. It is proportionately narrower toward the beak.

The species derives its specific name from its occurrence on Random Island.

FORMATION AND LOCALITY.—Upper Cambrian: (6y) Sandstone on north side of Random Island, between Birch and Sandy points, Smith Sound, Trinity Bay, Newfoundland.

LINGULELLA ROTUNDA (Matthew).

Plate XXXVII, figures 3h-k.

Lingulepis rotunda MATTHEW, 1903, Geol. Survey Canada, Rept. Cambrian Rocks Cape Breton, p. 199, Pl. XIV, figs. 4a-f. (Described and discussed as a new species.)

This small species is marked by its nearly circular, convex dorsal valve. The inner surface of the shell is strongly punctate, but I could not find the minute tubercles on the outer surface of the dorsal valve described by Matthew. The outer surface, where preserved, appears to be smooth or marked by concentric striae.

FORMATION AND LOCALITY.—Middle Cambrian: (325a [*Matthew, 1903, p. 199*]) *Shales of Division C2c of Matthew's [1903, p. 49] Bretonian, on the eastern slope of the valley of McNeil Brook, on the road to Trout Brook, in the Mira River valley; (3i) in compact, fine-grained, thin-bedded, gray sandstone, of the Paradorides zone, on McLean Brook, 1 mile (1.6 km.) east of McCodrum Brook, and 1.5 miles (2.4 km.) west of Marion Bridge; and (325c) sandstone on the shore of Bras d'Or Lake; all in eastern Cape Breton, Nova Scotia, Canada.*

LINGULELLA SCHUCHERTI (Walcott).

Plate XXI, figure 6.

Obolus (Lingulella) schucherti WALCOTT, 1901, Proc. U. S. Nat. Mus., vol. 23, pp. 689-690. (Described and discussed as below as a new species.)

General form elongate ovate, ventral valve subacuminate and the dorsal valve elongate ovate in outline. Surface marked by fine concentric striae, and rather strong concentric undulations or lines of growth; also fine radiating striae, and on some specimens indistinct, radiating, rather narrow, depressed furrows.

The outer surface of the inner layers shows radiating striæ and concentric lines of growth. The radiating striæ are also present on the inner surface outside of the area of the vascular cavity.

The shell is thick and formed of a thin outer layer and several thin inner layers or lamellæ arranged very much as in other shells of the genus *Lingulella*. The largest ventral valve has a length of about 11 mm.; width, 7 mm. A dorsal valve 8 mm. in length has a width of 5.5 mm.

Casts of the interior of the ventral valve show a well-marked area, with a broad, strong pedicle furrow. The base of the area arches strongly forward. Just at the center, across the pedicle furrow, however, it has a slight backward arch. None of the specimens show the flexure line or the extent of the area along the cardinal slopes of the valve. The area of the dorsal valve is unknown. None of the characters of the visceral cavity or vascular markings are shown with sufficient clearness to describe them. A tubercle on each side of the median line, just in advance of the area, indicates the main vascular sinus, and a depression the position of the anterior portion of the visceral cavity.

Observations.—This is probably the oldest species of the genus *Lingulella*. It is associated with *Botsfordia cæolata* (Hall), *Elliptocephala asaphoides* Emmons, and other characteristic species of the Lower Cambrian. In its elongate dorsal valve it recalls *Obolus rhea* Walcott of the Middle Cambrian (Pl. IX, figs. 1, 1a-c). It differs from that species in the character of the shell and the outline of the valve.

The specific name is given in honor of Prof. Charles Schuchert, who collected the only specimen of the species known to me.

FORMATION AND LOCALITY.—Lower Cambrian: (367) Conglomerate and limestone, Troy, Rensselaer County, New York.

LINGULELLA SIEMIRADZKII (Walcott).

Plate XXXI, figures 2, 2a.

Lingula sp. cf. *exunguis* Eichwald, SIEMIRADZKI, 1886, Jahrb. K.-k. geol. Reichsanstalt für 1886, Bd. 36, Hft. 4, p. 672. (Mentioned in German.)

Lingula cf. *exunguis* Eichwald, GÜRICH, 1892, Neues Jahrb. für Mineralogie, Bd. 1, p. 69. (Mentioned in German.)

Lingula sp. *Lingula* aff. *exunguis* Eichwald, GÜRICH, 1896, Verhandl. Russ.-kais. min. Gesell. St. Petersburg, 2d ser., Bd. 32, p. 214. (Discussed.)

Obolus (*Lingulella*) *siemiradzki* WALCOTT, 1901, Proc. U. S. Nat. Mus., vol. 23, pp. 690-691. (Discussed as below as a new species.)

Attention was called to this species by Siemiradzki [1886, p. 672] in connection with his study of the Paleozoic rocks of the Mittelgebirge of Poland. He speaks of it as "*Lingula* sp." in the black conglomerate, and compares it with "*L. exunguis* Eichwald." In the associated gray sandstone he found an *Obolus* which he says is identical with "*O. siluricus* Eichwald."

Gürich discusses the Cambrian of Sandomierz in a paper on the Paleozoic of the Mittelgebirge, and mentions [1896, p. 17] Siemiradzki's discovery of fossils in the lower sandstones and shales.

Gürich added greatly to the fauna found by Doctor Siemiradzki. He mentions [1896, p. 17] *Paradoxides* cf. *tessini*, *P. bohemicus*, *Agnostus fallax*, *A. gibbus*, and *Liostracus linnarsoni*, and refers the fauna to the Middle Cambrian. The "*Lingula*" he compares [1896, p. 214] with "*Lingula crassa* Eichwald," calling attention to the resemblance in the surface characters; also to those of *Lingulella davisii* (McCoy).

This is a small shell belonging to the group of species containing *Lingulella ferruginea* Salter, *L. desiderata* (Walcott), etc. The outer surface is marked by concentric, slightly undulating, and imbricating striæ of growth, and the outer surface of the inner layers by fine radiating striæ. The general form and other characters are represented in Plate XXXI, figures 2 and 2a.

Through the kindness of Dr. Fr. Schmidt I received a fragment of gray quartzitic sandstone containing a large number of specimens of the "*Lingula*" of Siemiradzki. The shell

proves to be a true *Lingulella*. In the same piece of rock an obscure form of *Obolus* occurs that may be a medium-sized *Obolus apollinis* Eichwald. I take pleasure in naming the *Lingulella* after its discoverer, Dr. J. S. Siemiradzki.

FORMATION AND LOCALITY.—Middle Cambrian: (368) Quartzitic sandstone in the Pepper Mountains, near Sandomierz, on the Vistula, Russian Poland.

LINGULELLA ? SIGNATA (Barrande).

Plate XXX, figure 11.

Lingula ? signata BARRANDE, 1868, Faune silurienne des environs de Hof, en Bavière, p. 103, fig. 73. (Described and discussed in French as a new species. Fig. 73 is reproduced in this monograph, Pl. XXX, fig. 11.)

Lingula ? signata BARRANDE, 1868, Neues Jahrb. für Mineralogie for 1868, p. 692, unnumbered plate, fig. 73. (Copy of preceding reference.)

This species is doubtfully referred to *Lingula* by its author. It is oval in outline, with a strongly arched surface. Where the shell is partly removed two small, elongate impressions are seen near what is supposed to be the posterior portion of the valve, and on the front portion of the shell a longitudinal groove. Barrande [1868a, p. 103] remarks that the latter recalls the perforation of *Discina*; but it is not perforated, as the shell continues over the entire surface of the depression. The aspect of the shell is horny and without ornamentation. Length, 2.5 mm.; width, 2 mm.

It is very doubtful if this species should be referred to *Lingulella*, but it may possibly be a rounded dorsal valve somewhat like that of *L. mosia* (Hall), *L. ferruginea* Salter, or *Lingulella (Lingulepis) acuminata* (Conrad).

FORMATION AND LOCALITY.—Passage beds between the Upper Cambrian and the Ordovician: (303c [Barrande, 1868a, p. 103]) Suburbs of Hof, Bavaria, Germany.

LINGULELLA SIMILIS (Walcott).

Plate XXI, figures 2, 2a-j, 3, 3a-d.

Obolus (Lingulella) similis WALCOTT, 1898, Proc. U. S. Nat. Mus., vol. 21, pp. 415-416. (Described and discussed as below as a new species.)

Shell small, general form ovate, with the ventral valve subacuminate, and the dorsal valve rounded ovate in outline. There is some variation in the outline of the valves; this may be seen by comparing Plate XXI, figures 2 and 2b, of the ventral valve, and figures 2a and 2c of the dorsal valve. Surface of the shell marked by concentric lines of growth and very fine, slightly irregular, concentric striæ. Where the outer surface is well preserved, fine radiating striæ may be seen with a strong magnifying glass. When the outer layer of the shell is exfoliated the outer surface of the inner layer is marked by fine concentric lines and very fine numerous radiating striæ; the inner surface of the shell shows concentric lines of growth and faint, scattered pits or punctæ. The shell is of medium thickness and formed of a thin outer layer, with one or more inner layers or lamellæ. The latter are especially prominent toward the front, where they have essentially the same arrangement as in *Lingulella acutangula* (Roemer). The average length of the ventral valve is from 4 to 5 mm.; width, 2.5 mm. An associated dorsal valve 4 mm. in length has a width of 3 mm.

A cast of the interior of a ventral valve shows a clearly defined area of medium length. It is divided midway by a cast of a narrow, strong pedicle furrow, and on each side by flexure lines situated about two-thirds the distance from the pedicle furrow to the lateral margin; a few indistinct striæ cross the area parallel with its base. The area of the dorsal valve as seen in a cast is well defined and rather large; it is marked by fine, transverse striæ of growth and indistinct flexure lines. A cast of the interior of the dorsal valve shows a trace of the visceral cavity and a narrow median septum. The only muscle scars observed are the two umbonal scars in the ventral valve (g), figure 2, and the central (h) and the anterior lateral scars (j) of the dorsal valve, figure 2a.

Observations.—This very pretty little species occurs in abundance in the compact gray limestone of the Black Hills associated with numerous fragments of trilobites and *Dicellomus nanus* (Meek and Hayden). The more elongate forms strongly resemble *Lingulella perattenuata* (Whitfield), which occurs in the Middle Cambrian sandstones on the southern margin of the Black Hills. The species differs, however, from the latter in being more ovate and in having the dorsal valve more obtusely rounded posteriorly. This species may be also compared with *L. desiderata* (Walcott) and *L. manticula* (White). When flattened in the shales it is difficult to distinguish it from *L. desiderata*.

A small shell occurs in the "St. Croix sandstone" of the upper Mississippi region that appears to be identical with this species, both in its typical form and in its comparatively wide range of variation. With the somewhat abundant supply of material from both the Black Hills and Wisconsin, I am unable to determine any specific differences that are constant. The same is true of the form in the limestones south-southwest of Potosi, Missouri, where it is associated with *Linnarssonella girtyi* Walcott.

The same range of variation occurs in shells from the limestone in the upper part of the Reagan sandstone of Oklahoma, and apparently they are identical.

In the shaly sandstones of the Rome formation in Tennessee casts of an apparently identical form occur (Pl. XXI, figs. 3, 3a-d). The variation between the Tennessee and South Dakota shells does not appear to be greater than the range of variation among the shells from the same locality in the Black Hills and the localities where it has been identified in Wisconsin and Minnesota.

In a limestone at the north end of the Quinn Canyon Range, Nevada, J. E. Spurr, of the United States Geological Survey, collected a number of small shells that appear to be identical with this species. The shells are well preserved and have the general form of surface characteristic of the species. A single specimen of a larger ventral valve has all the characteristics of *L. manticula* (White).

A shell from Middle Cambrian limestones at Mount Nebo, Wasatch Range, Utah, is doubtfully referred to this species. It is associated with *Micromitra (Iphidella) pannula* (White) and *Acrotreta neboensis* Walcott.

This form owes its specific name to its marked resemblance to several other forms, from each of which, however, it is distinct.

FORMATION AND LOCALITY.—**Upper Cambrian:** (12m) Arbuckle limestone (in the section 7 miles (11.2 km.) north of Springer this horizon is about 30 feet (9.1 m.) above the Reagan sandstone), in NE. $\frac{1}{4}$ sec. 2, T. 2 S., R. 1 E., Ardmore quadrangle (U. S. Geol. Survey), Carter County, Oklahoma.

(12n) Limestone of the Reagan sandstone (in the section 7 miles (11.27 km.) north of Springer this horizon is about 240 feet (73 m.) above the porphyry contact and 40 feet (12 m.) below the Arbuckle limestone), NW. $\frac{1}{4}$ sec. 1, T. 2 S., R. 1 E., Ardmore quadrangle (U. S. Geol. Survey), Carter County; (12k) limestone of the Reagan sandstone (in the section 7 miles (11.2 km.) north of Springer this horizon is about 225 feet (69 m.) above the porphyry contact and 55 feet (17 m.) below the Arbuckle limestone), on the west side of Honey Creek, near the southeast corner of sec. 35, T. 1 S., R. 1 E., Ardmore quadrangle (U. S. Geol. Survey), Carter County; (12p) about 225 feet (69 m.) above the igneous rocks in the limestone of the Reagan sandstone, at the northwest extremity of the Arbuckle Mountains, about 4 miles (6.4 km.) east of Homer, Carter County; all in Oklahoma.

(9r) About 45 feet (14 m.) above the porphyry contact in the limestone of the Reagan sandstone, SE. $\frac{1}{4}$ NE. $\frac{1}{4}$ sec. 2, T. 4 N., R. 13 W.; (9s) about 85 feet (26 m.) below the Arbuckle limestone in the limestone of the Reagan sandstone, middle of west half of sec. 13, T. 4 N., R. 13 W.; (9t) about 170 feet (52 m.) above the porphyry contact in the limestone of the Reagan sandstone, SE. $\frac{1}{4}$ NE. $\frac{1}{4}$ sec. 2, T. 4 N., R. 13 W.; and (9u) about 195 feet (59.4 m.) above the porphyry contact in the limestone of the Reagan sandstone, SE. $\frac{1}{4}$ NE. $\frac{1}{4}$ sec. 2, T. 4 N., R. 13 W.; all about 15 miles (24.2 km.) northwest of Fort Sill, Comanche County, Oklahoma.

(328a) "St. Croix sandstone" 4 miles (6.4 km.) north of Winfield; and (97a and 97c) "St. Croix sandstone" near Winfield; both in Jefferson County, Wisconsin.

(78b) "St. Croix sandstone" 50 feet (15.2 m.) above St. Croix River, near the landing at Osceola, Polk County; (328n) "St. Croix sandstone" 2 miles (3.2 km.) south of Osceola, Polk County; and (80a) "St. Croix sandstone" 4 miles (6.4 km.) north of Reedsburg, Sauk County; all in Wisconsin.

(86a) "St. Croix sandstone" near Redwing, Goodhue County; (339d) "St. Croix sandstone" at Taylors Falls, Chisago County; (82c) conglomerate beds in the "St. Croix sandstone" in point below Franconia, Chisago County;

(97s) "St. Croix sandstone" at Franconia, Chisago County; and (97) "St. Croix sandstone" at Reads Landing, foot of Lake Pepin, Wabasha County; all in Minnesota.

Middle Cambrian: (7j) Limestones at the north end of the Quinn Canyon Range, 1 mile (1.6 km.) northwest of the Italian Ranch foothills, Nye County, Nevada.

(360d) Siliceous limestones near Pike View, north of Colorado Springs, El Paso County, Colorado.

(355a) Shales in Bear Gulch Valley; (88a) limestone about 100 feet (30.5 m.) above the quartzitic sandstone at the base of the Cambrian in the northern suburbs of Deadwood; (165) limestone on the east side of the valley, in railroad cut about 1 mile (1.6 km.) below the main part of Deadwood; and (17j) limestone in the east end of the town of Galena; all in the Black Hills, South Dakota.

(11e) Thin-bedded limestones south-southwest of Potosi, Washington County, Missouri.

(10a) Sandy layers of the Rome formation, in western railroad cut through Shooks Gap, and (106) shales of the Rome formation, on the roadside at the eastern base of Shooks Gap; both in Bays Mountains, 10 miles (16.1 km.) southeast of Knoxville [Keith, 1895, areal geology sheet], Knox County, Tennessee.

(9a) Limestone on the south shore of the Holston River at Melinda Ferry, 5 miles (8 km.) southwest of Rogersville [Keith, 1896a, areal geology sheet], Hawkins County, Tennessee.

(14a) Sandstone of the Rome formation along First Creek Gap, 4 miles (6.4 km.) north-northeast of Knoxville [Keith, 1905, areal geology sheet], and (374) in the suburbs of and 4 and 11 miles (6.4 and 17.7 km.) north-northeast of Knoxville; both in Knox County, Tennessee.

(138) Shale in the street northeast of Printz House, Gadsden, Etowah County, and (145) shale in bluff on Coosa River east of Turkeytown, 8 miles (12.8 km.) northeast of Gadsden, Etowah County; both in Alabama.

(362a) Sandy shale a short distance west of Cave Spring; (138a) shales in the Rome formation west of the cemetery west of Rome; and (140c) shales at edge of hill on the road leading west of Cave Spring; all in Floyd County, Georgia.

Specimens that are somewhat doubtfully referred to this species occur at the following localities:

Middle Cambrian: (14t) Limestone lying on slope between the Cambrian quartzite and the massive blue limestone 100 feet (30.5 m.) above, Mount Nebo Canyon, 3 miles (4.8 km.) southeast of Mona, Juab County, Utah.

(92x) Conasauga ("Coosa") shale, at Yanceys Bend, Coosa River; and (90) Conasauga ("Coosa") shale on Edwards's farm, near Craigs Mountain; both southeast of Center, Cherokee County, Alabama.

LINGULELLA? SIMPLEX (Barrande).

Plate XXXII, figures 4, 4a-b.

Lingula simplex BARRANDE, 1879, *Système silurien du centre de la Bohême*, vol. 5, pt. 1, Pl. CIV, figs. vi: 1-4. (Not described, but figured as a new species. Figs. 1A, 4A, and 4B are reproduced in this monograph, Pl. XXXII, figs. 4, 4a-b, respectively.)

This species, like *Lingulella? insons* (Barrande), is one of the forms that, with the present evidence, is probably to be referred to *Lingulella*. All that is known to me of the species is shown in the figures copied from Barrande.

FORMATION AND LOCALITY.—**Lower Ordovician:** (303a) Étage D3 at Trubin; and (303p) Étage d3 in the environ. of Beraun; both [Barrande, 1879b, Pl. CIV] in Bohemia, Austria-Hungary.

LINGULELLA TARPA (Walcott).

Plate XXIII, figures 2, 2a-c.

Obolus (Lingulella) tarpa WALCOTT, 1898, *Proc. U. S. Nat. Mus.*, vol. 21, pp. 417-418. (Described and discussed as below as a new species.)

General form elongate ovate, with the ventral valve subacuminate, and the dorsal valve ovate in outline. There is considerable range of variation in the outline of both valves, owing in part, possibly, to distortion. The convexity of the two valves is fairly strong, as far as can be determined from the somewhat compressed condition of the shells in the shale and calcareous sandy shales. The largest ventral valve in the collection has a length of 14 mm. The average length of the ventral valve is from 10 to 12 mm. One 11.5 mm. in length has a width of 8 mm.

None of the specimens of the collection show the outer surface, and only traces of concentric and radiating lines have been observed on the inner surface. The shell appears to be moderately thick, and formed of numerous lamellæ that were oblique to the outer layer in the

anterior portions of the shell, in this respect resembling the shell of *Lingulella acutangula* (Roemer) (Pl. XVII, figs. 1m, 1o).

Casts of the interior of the ventral valve have a moderately long area divided midway by the cast of a strong pedicle furrow and marked about midway between the pedicle furrow and the lateral margin by a sharp flexure line; striæ of growth cross the area parallel with its base and arch over the cast of the pedicle furrow. The area of the dorsal valve is relatively short, arching forward slightly at the median portion. The only interior markings observed are seen in the casts of the ventral valve where the visceral area and a portion of the main vascular sinuses are imperfectly preserved.

Observations.—The external form of this species strongly recalls that of *Lingulella acutangula* (Roemer), but the material is too imperfect to identify it with the latter. It occurs at a considerably lower geologic horizon, and what is preserved of the interior markings of the ventral valve indicates a considerable difference in the position of the visceral area (Pl. XVII, fig. 1c, and Pl. XXIII, fig. 2a).

FORMATION AND LOCALITY.—**Middle Cambrian:** (11) *Sandstones and shales of the Rome formation, about 1 mile (1.6 km.) east of Post Oak Springs [Hayes, 1894, areal geology sheet], Roane County;* and (11a) sandstone between First and Armstrong creeks, in the southeast corner of the Maynardville quadrangle (U. S. Geol. Survey), Union County; both in Tennessee.

LINGULELLA TEXANA Walcott.

Plate XLIX, figures 3, 3a.

Lingulella texana WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 3, p. 71, Pl. VIII, fig. 5. (Characterized as below as a new species. Fig. 5 is copied in this monograph, Pl. XLIX, fig. 3.)

This is a small but distinctly marked species, represented by two dorsal valves occurring in the Upper Cambrian limestones of central Texas. The dorsal valves are oval, and quite strongly convex. The shell appears to have been rather thick, and the outer surface is marked by strong, radiating striæ, a feature which is characteristic of the species. They are crossed by fine, concentric striæ and lines of growth. The position of the muscle scars and the size and character of the area are shown by Plate XLIX, figure 3a.

FORMATION AND LOCALITY.—**Upper Cambrian:** (369) Sandstones at the base of the Elvins formation, in the eastern limits of the town of Flat River, St. Francois County, Missouri.

(69) Limestones near Honey Creek; and (70) limestone near *Morgans Creek*; both in Burnet County, Texas.

LINGULELLA TORRENTIS (Matthew).

Plate XXXV, figure 7.

Leptobolus torrentis MATTHEW, 1903, Geol. Survey Canada, Rept. Cambrian Rocks Cape Breton, pp. 74-75, Pl. VI, fig. 1. (Described as below as a new species. The specimen represented by fig. 1 is redrawn in this monograph, Pl. XXXV, fig. 7.)

Leptobolus atavus tritavus MATTHEW, 1903, idem, p. 109, Pl. VI, figs. 5a-c. (Characterized as a new variety.)

The original description by Matthew follows:

Shell thin, surface shining. Form elongate oval.

Ventral valve obtusely pointed at the back, somewhat acutely rounded in front; elevated along the middle; somewhat flattened along the sides within the margin.

By decortication a low boss and a transverse furrow behind it are exposed on the mold, about three-quarters of the length of the valve from the hinge; if this boss marks the front of the callus, the central muscles are unusually far forward, more advanced even than in *L. atavus* of the Etcheminian terrane. There are faint impressions of the lateral septa on the sides of the valve.

The surface of the shell is covered with minute, low tubercles, cancellate in arrangement; through these can be traced faint parallel lines, concentric to the umbo. Along the median third in places can be seen about six broad, flat ridges, radiating from the direction of the umbo; these break the continuity of the concentric ridges.

Length, 3 mm.; width, 2 mm.; depth, 0.5 mm.

The ventral valve of "*Leptobolus atavus tritavus*" Matthew is similar in form to the type of *Lingulella torrentis*. Compare figures 1 and 5a of Matthew [1903, Pl. VI]. The surface characters

appear to be identical. The dorsal valve is elongate oval in outline, resembling the same valve in *Lingulella atava* (Matthew).

FORMATION AND LOCALITY.—Middle Cambrian: (344f [Matthew, 1903, p. 72]) Shales of the Coldbrook terrane of Matthew, on Dugald Brook, Indian River; and (344e [Matthew, 1903, p. 78]) shales of Division E1d of Matthew's [1903, pp. 28 and 29] Etcheminian, on Boundary Brook, eastern side of the Escasonie Indian Reservation; both in eastern Cape Breton, Nova Scotia.

LINGULELLA TRIPARILIS (Matthew).

Text figures 44a-l, page 537; Plate XLV, figures 2, 2a-f.

Obolus triparilis MATTHEW, 1902, Trans. Roy. Soc. Canada, 2d ser., vol. 8, sec. 4, No. 3, p. 94, Pl. I, figs. 2a-c. (Discussed as a new species.)

Obolus discus MATTHEW, 1902, idem, p. 94, Pl. I, figs. 3a-d. (Mentioned as a new species.)

Lingulella longovalis MATTHEW, 1903, Geol. Survey Canada, Rept. Cambrian Rocks Cape Breton, pp. 123-125, Pl. VII, figs. 3a-f. (Described and discussed as a new species. Figs. 3b and 3d are represented in outline by text figs. 44h and 44h', respectively, p. 537, of this monograph.)

Obolus (Eoobolus) triparilis MATTHEW, 1903, idem, pp. 136-137, Pl. VIII, figs. 4a-c; Pl. IX, figs. 1a-b. (Described and discussed as a new species. Pl. VIII, figs. 4a-c, is copied from Matthew, 1902b, Pl. I, figs. 2a-c; Pl. VIII, fig. 4a, and Pl. IX, fig. 1a, are represented in outline by figs. 44b and 44b', respectively, p. 537, of this monograph.)

Obolus (Eoobolus) discus MATTHEW, 1903, idem, pp. 138-139, Pl. VIII, figs. 3a-d. (Described and discussed as a new species. Figs. 3a-d are copied from Matthew, 1902b, Pl. I, figs. 3a-d; figs. 3a and 3c are represented in outline by figs. 44a and 44a', respectively, p. 537, of this monograph.)

This species is distinguished from *Lingulella (Lingulepis) gregwa* (Matthew) by its outline. The range of variation in its form covers both the types of the species and the types of "*Lingulella longovalis*" Matthew and "*Obolus (Eoobolus) discus*" Matthew. Matthew assigns specific value to variations in length and breadth of the visceral areas of the valves. I do not find that this holds good, as the shells from the same layer of rocks and not distinguishable by other characters vary in the length of the visceral area of the dorsal valve from a point back of the center to nearly the front of the valve. There is also considerable variation in the ventral valve. On the same shell there is a variation of the surface characters from the nearly plain, concentric striae to undulating striae, with minute points on the crest. This is also true of the surface of *Lingulella (Lingulepis) gregwa* (Matthew).

The "central" scar in the dorsal valve, mentioned by Matthew [1903, p. 136] as characterizing "*Obolus (Eoobolus) triparilis*," is at the bifurcation of the median ridge, and appears to be a slight depression just in advance of the bifurcation and not a true muscle scar. The variation in outline of the valves is shown in figures 44a-l.

No specimens among the types sent by Matthew nor in our material show areas like those represented by figures 44b' and 44h'. The area is not preserved on the dorsal valves of *L. triparilis* sent by Matthew, and the area of the dorsal valve of his "*L. longovalis*" does not extend so far down the lateral slopes of the shell as represented in the figure.

The variation in the length and strength of the visceral area in the two valves is also outlined from specimens showing their position. Among the specimens from the same layer of rock there is a transition in form from *Lingulella triparilis* to *Lingulella (Lingulepis) longinervis* (Matthew) of a somewhat later stratigraphic horizon. This is illustrated in figures 44f-k.

The surface characters are of the same type in *Lingulella (Lingulepis) gregwa* (Matthew), *L. (L.) longinervis* (Matthew), and *Lingulella triparilis*.

"*Obolus (Eoobolus) discus*" Matthew appears to be based on imperfect specimens of the short, broad form of *L. triparilis*. With the types of "*O. (E.) discus*," *L. triparilis*, and "*L. longovalis*" before me, I am not able to discover differences of specific value between them. All have the same surface characters, and the gradations in form unite them into one species.

FORMATION AND LOCALITY.—Middle Cambrian: (13t' and 13t)^a Sandstones at the base of Division E1b; (344g) [Matthew, 1903, p. 77] shales of Division E1c; (13t'') sandstones of Divisions E1c and E1d; (344h [Matthew, 1903,

^a 13t is the type locality, though the specimens in the United States National Museum collections to which that number was assigned were collected later than Matthew's type specimens.

p. 79] sandy layers in the shales of Division E1c; and (10p) sandstone just below the waterfall in Division E2b; all in Matthew's [1903, p. 21] Etcheminian, on Dugald Brook, Indian River Valley, eastern Cape Breton, Nova Scotia.

(307d [Matthew, 1903, p. 79]) Sandy limestone of Division E2a? of Matthew's Etcheminian, on Young (McFees) Point, George River, Cape Breton, Nova Scotia.

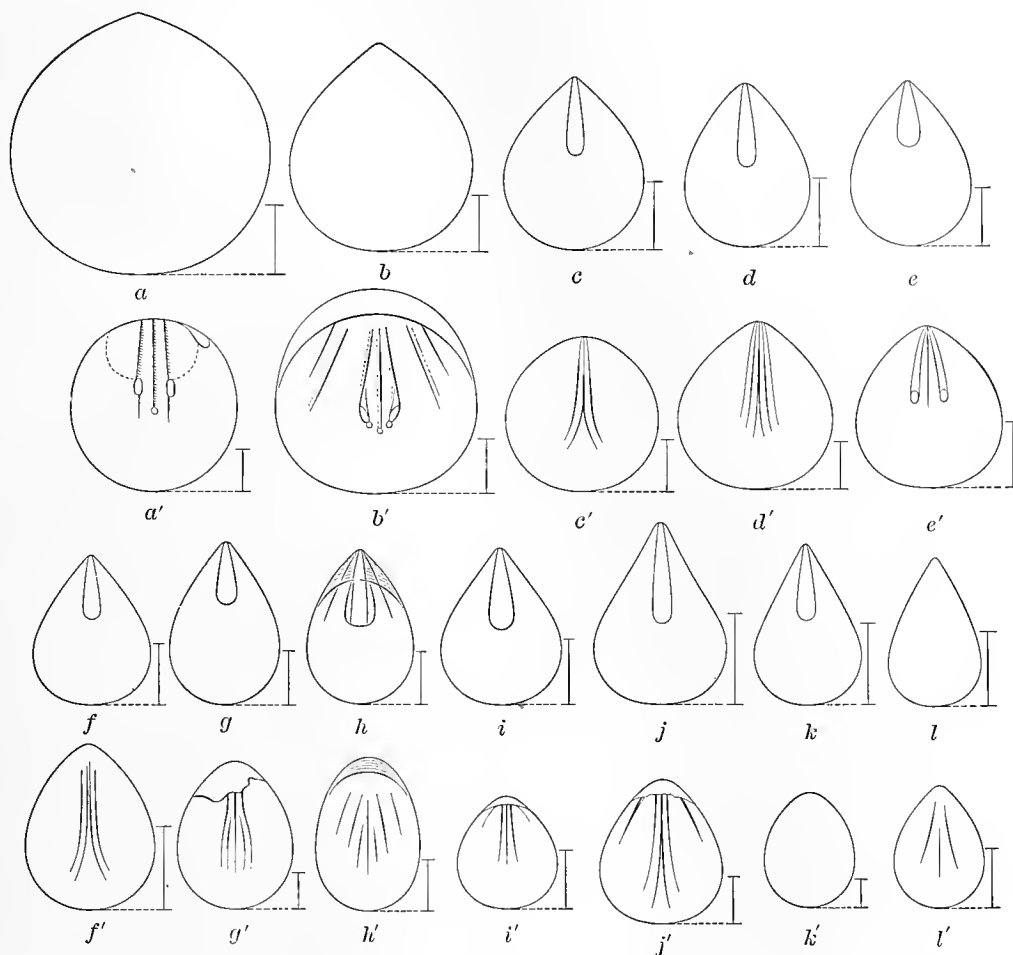

FIGURE 44.—*Lingulella triparilis* (Matthew); outlines illustrating variation in form of shells now referred to *Lingulella triparilis*. *a, a'*, Ventral and dorsal valves of "*Obolus (Eoobolus) discus*" [Matthew, 1903, Pl. VIII, figs. 3a and 3c]. *b, b'*, Ventral and dorsal valves of *Lingulella triparilis* [Matthew, 1903, Pl. VIII, fig. 4a, and Pl. IX, fig. 1a]. *c-g, c'-g'*, Ventral and dorsal valves from Locality 13t', sandstones of Division E1c of Matthew, Dugald Brook, illustrating the gradation in form between shells referred to *L. triparilis* and "*L. longovalis*." *h, h'*, Ventral and dorsal valves of "*L. longovalis*" [Matthew, 1903, Pl. VII, figs. 3b and 3d]. *i-l, i'-l'*, More elongate ventral and dorsal valves from specimens associated with those represented by *c-g*.

LINGULELLA TUMIDA Matthew.

Plate XXIV, figures 7, 7a-d.

Lingulella tumida MATTHEW, 1899, Bull. Nat. Hist. Soc. New Brunswick, vol. 4, pt. 3, No. 18, p. 200, Pl. I, figs. 2a-c. (Described as a new species.)

Obolus (Lingulepis) gregwa WALCOTT (in part) [not (MATTHEW)], 1901, Proc. U. S. Nat. Mus., vol. 23, p. 692-694. (Matthew's *Lingulella tumida* is here referred to and described with *Lingulella (Lingulepis) gregwa*.)

Lingulella tumida MATTHEW, 1903, Geol. Survey Canada, Rept. Cambrian Rocks Cape Breton, p. 123, Pl. VI, figs. 6a-c. (Described and discussed. Figs. 6a-c are copied from Matthew, 1899b, Pl. I, figs. 2a-c.)

This shell resembles *Lingulella martinensis* Matthew and some forms of *Lingulella (Lingulepis) exigua* (Matthew) in outline of the valves. At first I thought it should be placed with the latter species, which I had [1901, p. 692] by error identified with *Lingulella (Lingulepis) gregwa* (Matthew). It is uniformly smaller than *L. (L.) exigua*, and differs in the more uniform concentric lines and striae of growth.

Matthew's material is poor, but in the collections made by S. Ward Loper there is an abundance of specimens showing some variations in form. The surface is marked by strong, concentric lines of growth, with narrow bands of finer and somewhat minutely irregular striæ. Depressed, irregular, and bifurcating radiating lines show on very perfectly preserved shells.

FORMATION AND LOCALITY.—Middle Cambrian: (13i) Sandstones of the "Johannian" Division of Matthew's section, on Gillis Brook, East Bay, east of Bras d'Or Lake; and (13r) sandstone at a little different horizon than that of Locality 13i, on Gillis Brook, East Bay, east of Bras d'Or Lake; and (13n')^a sandstones of Division *E3e* of Matthew's [1903, p. 21] Etcheminian, Dugald Brook, Indian River; all in eastern Cape Breton, Nova Scotia.

LINGULELLA UPIS (Walcott).

Plate XXXVI, figures 3, 3a.

Obolus (Lingulella) upis WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 331-332. (Described and discussed as below as a new species.)

This is a small, elongate shell of the group to which *Lingulella ora* (Walcott) belongs. It differs from the latter in being more elongate and in its marked surface characters, and from *L. collicia* (Matthew), *L. flumenis* (Matthew), *L. cania* (Walcott), and allied forms, in having a thick, strong shell and highly characteristic exterior surface.

The shell is thick, the anterior portions being made up of numerous lamellæ oblique to the exterior surface, in this respect resembling some of the species of *Obolus* having thick shells. The exterior surface is marked by concentric lines of growth, with very fine, somewhat irregular striæ between them. These show very distinctly in the anterior portion of the shell. Further back they become very irregular, giving a crenulated appearance to the striæ and lines of growth, and the surface looks as though it was formed of thin, imbricating scales or lamellæ.

Observations.—The surface of *Lingulella upis* suggests that of *Obolus (Westonia) euglyphus* (Walcott), but I have been unable to find traces of the transverse lines characteristic of *Westonia*.

FORMATION AND LOCALITY.—Upper Cambrian: (14g and 14i)^b Upper part of the limestones exposed 1 mile (1.6 km.) west of Cherokee, San Saba County; and (14b) limestone on Cold Creek, at north end of gorge opposite the north end of Sponge Mountain, 2 miles (3.2 km.) south of the San Saba County line, in Llano County; both in Texas.

LINGULELLA WANNIECKI Redlich.

Plate XXXIX, figures 1, 1a-n.

Lingulella wanniecki REDLICH, 1899, Mem. Geol. Survey India, Paleontologia Indica, new ser., vol. 1, No. 1, The Cambrian Fauna of the Eastern Salt Range, p. 7, Pl. I, figs. 9a-d. (Described and discussed as a new species.)

Obolus (Lingulella) wanniecki (Redlich), WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 332. (Described and discussed as below.)

General form broadly ovate, with the ventral valve obtusely acuminate and the dorsal valve rounded subtriangular; convexity moderate in the specimens embedded in argillaceous shales. There is considerable range of variation in the outline of the valves; this is shown in Plate XXXIX, for the ventral valve by figures 1, 1a-f, and for the dorsal valve by figures 1g-m. All that is known to me of the interior markings of the ventral valve is shown by figures 1d-f, and of the dorsal valve by figures 1l-n. The surface of the shell is marked by concentric lines of growth and very fine closely undulating raised striæ that inosculate so as to give the surface a granulated appearance. This type of surface occurs on *Lingulella isse* (Walcott) and *L. upis* (Walcott). The anterior layers of the shell are marked by radiating and concentric striæ, and the interior of the shell has scattered punctæ in addition to the radiating and concentric striæ. The shell is relatively thick and formed of several layers or lamellæ in addition to the very thin outer ornamented layer.

The visceral area of the ventral valve is short, and the main vascular sinuses are about halfway between the center of the shell and the lateral margins. In the dorsal valve the

^a 13n' is the type locality, but the specimens in the United States National Museum to which that number is assigned were collected later than the type specimens.

^b 14i is the type locality.

visceral area is well developed beyond the center of the shell, and the vascular sinuses are farther out proportionately than in the dorsal valve. The central and anterior lateral muscle scars are placed on an elevated central ridge, on each side of a sharp median septum.

Observations.—This very pretty little shell occurs in great numbers in the dark argillaceous shales with *Redlichia noctlingi* (Redlich). Redlich [1899, p. 7] states that it is the only species of the genus in the collection sent to him. In the collections made by Fritz Noetling I find associated with *Redlichia noctlingi*, *Lingulella wanniecki*, *L. fuchsi* Redlich, *Acrothelæ* (*Redlichella*) *granulata* (Linnarsson); also specimens of a species of undescribed *Hyolithes*.

Among the American species of *Lingulella*, *L. wanniecki* may be compared in form with *L. desiderata* (Walcott) and *L. oweni* (Walcott). Its surface is much like that of *L. upis* (Walcott) and *L. ora* (Walcott). It is distinct from all described species when its form and surface are taken into consideration, as there is no species with its subtriangular form that has its granulated surface.

The formations containing this fauna are referred to the Middle Cambrian, as there is no evidence that the Cambrian fauna of India above the upper "Annelid sandstone," as described by Noetling and Redlich, is older.

FORMATION AND LOCALITY.—Middle Cambrian: (15r) ^a Dark argillaceous shales at Khussak, Salt Range, India.

LINGULELLA WELLERI (Walcott).

Plate XXXVIII, figures 4, 4a-b.

Obolus (*Lingulella*) *welleri* WALCOTT, 1902, Proc. U. S. Nat. Mus., vol. 25, p. 608. (Described and discussed essentially as below as a new species.)

General form elongate ovate, with the ventral valve subacuminate and the dorsal valve subelliptical. Owing to the more or less crushed condition of all the specimens the exact convexity of the entire valve is unknown. Surface of the shell marked by numerous elevated concentric lines of growth and very fine slightly irregular interstitial concentric striæ.

When the outer edge is exfoliated the inner layers show fine radiating striæ and concentric lines of growth. Nothing is known of the interior surface of the shell. The shell appears to have been relatively thin and formed of several layers or lamellæ.

A ventral valve 14 mm. in length has a width of 9 mm. and a dorsal valve 10 mm. in length has a width of 7.5 mm. In both valves the width is slightly increased by the flattening of the shell.

Observations.—This species occurs in association with *Obolus* (*Westonia*) *stoneanus* (Whitfield) in an arenaceous, magnesian limestone. It differs from described species of *Lingulella* in the elliptical form of its dorsal valve and the strongly filose concentric striæ of the outer surface.

The dorsal valve has the outline of that of *Obolus* (*Westonia*) *stoneanus* but the ventral valve is more acuminate and the characteristic *Westonia* surface of the latter is absent. Some specimens of *O.* (*W.*) *stoneanus* have the transverse imbricating lines only on the posterior half of the valve, in which case the anterior half is much like that of *Lingulella welleri*.

The specific name is given in honor of Prof. Stuart Weller, who discovered the locality.

FORMATION AND LOCALITY.—Upper Cambrian: (11c) Hardyston quartzite [Weller, 1900, pp. 10 and 12], O'Donnell and McManniman's quarry, Newton, Sussex County, New Jersey.

LINGULELLA WINONA (Hall).

Plate XVIII, figures 3, 3a-b.

Lingula winona HALL, 1863, Sixteenth Rept. New York State Cab. Nat. Hist., p. 126, Pl. VI, fig. 9. (Described as a new species; see p. 540 for copy.)

Lingula winona HALL, 1867, Trans. Albany Inst., vol. 5, p. 102, Pl. I, fig. 9. (Copied from preceding reference.)

^a Specimens from the type locality were given to the United States National Museum and this number was assigned to them.

Lingula winona Hall, SARDESON, 1896, Bull. Minnesota Acad. Nat. Sci., vol. 4, No. 1, pt. 1, p. 96. (Characterizes specimens from new locality.)

Lingulella winona (Hall), SCHUCHERT, 1897, Bull. U. S. Geol. Survey No. 87, p. 258. (Merely changes generic reference.)

The original description by Hall follows:

Shell small, subquadrilateral, the front nearly straight; sides nearly straight and parallel; apex obtuse, the cardinal margins sloping at an angle of 80 degrees. Surface marked by fine concentric striae.

A cast of part of a ventral valve from Osceola, Wisconsin, that appears to belong to this species, shows the visceral area and the main vascular sinuses (Pl. XVIII, fig. 3). This shell is more convex and has a more rounded outline than the type shell, but I think that this is owing to the fact that the type shells are pressed flat in the sandy shales and to a degree distorted. Flattened shells at Osceola are much more quadrate in outline.

The species has been found at a number of localities, but very little more can be added to the original description. The shell, although very small, is built up of two or more layers that are lamellose toward the front of the shell. The outlines of the two valves when compressed are shown by Plate XVIII, figures 3a and 3b.

The nearest form to *Lingulella winona* is *L. mosia* (Hall) of the Upper Cambrian. It differs in the uniformly smaller size and its regular subquadrate outline.

The specific name is derived from Winona, Minnesota.

FORMATION AND LOCALITY.—Upper Cambrian: (78 and 78c) "St. Croix sandstone," quarry near St. Croix River in suburbs of Osceola, Polk County; (85x) upper beds of the "St. Croix sandstone" near Mazomanie, Dane County; (10v) shaly beds in the "St. Croix sandstone," at Fox Glen, 8 miles (12.8 km.) east of Baraboo, Baraboo quadrangle (U. S. Geol. Survey), Sauk County; (79) "St. Croix sandstone" in bluff near Hudson, St. Croix County; and (85s) "St. Croix sandstone" at Prairie du Sac, Sauk County; all in Wisconsin.

(113) "St. Croix sandstone" at La Grange Mountain (or Barn Bluff), near Red Wing, Goodhue County, Minnesota.
(341) Near Lansing, Allamakee County, Iowa.

LINGULELLA WINONA CONVEXA (Walcott).

Plate XVIII, figures 4, 4a-d.

Obolus (*Lingulella*) *winona convexus* WALCOTT, 1901, Proc. U. S. Nat. Mus., vol. 23, p. 691. (Discussed as below as a new variety.)

A small relatively convex shell occurs abundantly in the brown sandstones at Osceola that appears to be an intermediate form between *Lingulella winona* (Hall) and *L. mosia* (Hall). It differs from *L. mosia* in being a shorter shell, and from *L. winona* in the more regularly ovate to semicircular dorsal valve and more acuminate ventral valve.

Observations.—The group of shells represented by *L. winona*, *L. mosia*, and their varieties appears to range from the Middle Cambrian beds of Hudson, Wisconsin, up and into the Upper Cambrian beds of Osceola, Wisconsin. There is so much variety of form owing to the conditions of preservation that it is very difficult to be always sure of the correctness of the specific reference. The variety *convexa* may be only the uncompressed form of *L. winona*, which is usually flattened in the shaly sandstones, or it may be a distinct species. From the material available for comparison this can not be clearly determined.

FORMATION AND LOCALITY.—Upper Cambrian: (78, 78s, and 78c)^a "St. Croix sandstone" in quarry near St. Croix River in suburbs of Osceola, Polk County; (79) "St. Croix sandstone" in bluff near Hudson, St. Croix County; (85x and 885x) upper beds of the "St. Croix sandstone," near Mazomanie, Dane County; (100) "St. Croix sandstone" near Menomonie, Dunn County; (79a) "St. Croix sandstone" in quarry and ledge, 0.5 mile (0.8 km.) southeast of the county courthouse, Menomonie, Dunn County; (80) "St. Croix sandstone" 0.66 mile (1.1 km.) southwest of the railway depot, Menomonie, Dunn County; (85s) "St. Croix sandstone" at Prairie du Sac, Sauk County; and (135) "St. Croix sandstone" near Trempealeau, Trempealeau County; all in Wisconsin.

(75) "Tonto" sandstone, near the water's edge at the mouth of Kanab Canyon, where it enters the Grand Canyon of the Colorado, Arizona.

^a 78 is the type locality.

LINGULELLA WIRTHI (Barrande).

Plate XXX, figure 7.

Lingula wirthi BARRANDE, 1868, Faune silurienne des environs de Hof, en Bavière, p. 101, fig. 63. (Described and discussed in French as a new species. Fig. 63 is reproduced in this monograph, Pl. XXX, fig. 7.)

Lingula wirthi BARRANDE, 1868, Neues Jahrb. für Mineralogie for 1868, p. 691, unnumbered plate, fig. 63. (Copy of preceding reference.)

This is a more elongate shell than *Obolus? bavaricus* (Barrande), and is known only by several casts. It has a length of 15 mm.; greatest width, 9 mm. In many respects it resembles *Lingulella davisii* (McCoy) of the *Lingula* flags of Wales. The outer surface is marked by concentric lines and striæ, as far as can be determined from the casts.

FORMATION AND LOCALITY.—**Passage beds** between the Upper Cambrian and the Ordovician: (303c [Barrande, 1868a, p. 101]) *Suburbs of Hof*; and (303f [Pompeckj, 1896a, pp. 7 and 8]) railway cut near Schellenberg, a little distance back of the railway station at Neuhof, near Hof; both in Bavaria, Germany.

LINGULELLA ZEUS n. sp.

Text figure 45.

This species is represented by one very minute specimen, a poorly preserved interior of a suborbicular ventral valve, showing a fairly well defined area. The exterior surface was covered with strong concentric striæ.

Observations.—This specimen is of particular interest as the only representative of the genus *Lingulella* from Scotland, where it occurs associated with *Olenelloides armatus*. The species is too poorly preserved for further description or comparison.

FORMATION AND LOCALITY.—**Lower Cambrian**: (316c) Shales from Locality M4197d of the Geological Survey of Scotland, a band probably equivalent to either 6 or 7 of the section on the north slope of Meall á Ghiubhais [Peach and Horne, 1907, p. 414] on the Bruachaig River, 2 miles (3.2 km.) east-northeast of the Kinlochewe Hotel, Loch Maree, Ross-shire, Scotland.

LINGULELLA sp. undt. a.

Plate XXX, figure 13.

There are two specimens of the dorsal valve in the collection from the *Olenus truncatus* zone. The outer surface is marked by fine radiating and concentric striæ, and the inner surface by large punctæ, scattered, as far as known, in the anterior half of the valve.

FORMATION AND LOCALITY.—**Upper Cambrian**: (310k) Oeland Island, Sweden.

LINGULELLA sp. undt. b.

Imperfect specimens of a small, rather broad form of *Lingulella* occur in Middle Cambrian shales at York, Pennsylvania. The outline of the shells is somewhat like that of *Obolus willisi* (Walcott), but the material is too poor for specific determination.

FORMATION AND LOCALITY.—**Middle Cambrian**: (48d) Argillaceous shales in the railroad cut beside the gas house, York, York County, Pennsylvania.

LEPTEMBOLON Mickwitz, subgenus of LINGULELLA.

[λεπτόλις, small; and ζηβολον, a wedge.]

Obolus (Leptembolon) MICKWITZ, 1896, Mém. Acad. imp. sci. St.-Petersbourg, 8th ser., vol. 4, No. 2, p. 199. (Characterized and discussed as a new subgenus; see below for translation.)

Obolus (Leptembolon) MICKWITZ, WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, no. 4, Pl. XI, and pp. 142 and 144. (Classification of subgenus.)

The original description by Mickwitz follows:

The subgenus *Leptembolon* is based on a species of *Obolus*, which externally resembles *Lingula* very closely, and in fact was by earlier authors regarded as such. The specimens of the internal surfaces of the valves, however,

FIGURE 45.—*Lingulella zeus* n. sp. Interior of a ventral valve, the type and only specimen, $\times 12$, from Locality 316c, Lower Cambrian shales near Loch Maree, Ross-shire, Scotland. The specimen is numbered M4197d in the collections of the Geological Survey of Scotland.

showed, together with some suggestions of the last-mentioned genus [*Lingula*], unmistakable marks of the genus *Obolus*, so that the species, which would not be assigned to any of the other groups, had to be ranked in a special subgenus of Eichwald's genus.

The internal characteristics of the Cambrian and Silurian *Lingulæ* have not hitherto been established so completely as to render it possible to compare the organization of this extinct group in detail with the recent *Lingula*. It is probable that more accurate knowledge of these oldest *Lingulæ* will lead to a change in the generic designation. A similar uncertainty of course exists also in regard to the relations of the genus *Obolus* to the above-mentioned *Lingulæ*, and if it be possible to ascertain the internal features of the latter to the same extent as in the genus *Obolus*, *O. linguliformis* will probably become the connecting link between these old extinct genera.

LINGULELLA (LEPTEMBOLON) LINGULÆFORMIS (Mickwitz).

Plate XIV, figures 5, 5a-b.

Obolus (Leptembolon) linguliformis MICKWITZ, 1896, Mém. Acad. imp. sci. St.-Pétersbourg, 8th ser., vol. 4, No. 2, pp. 200-204, Pl. III, figs. 10-17. (Described and discussed in German as a new species; see below for translation. Figs. 17a-b are copied in this monograph, Pl. XIV, fig. 5.)

Obolus (Leptembolon) linguliformis solidus MICKWITZ, 1896, idem, pp. 204-205, Pl. III, figs. 18 and 19. (Described and discussed in German as a new variety.)

The original description by Mickwitz follows:

Shells moderately large, quite flatly arched. Outline pointedly oval to subtriangular. Beak and posterior part of shell laterally somewhat flattened, forming two slightly pronounced roundish edges, which converge to the tip of the beak. Anterior part of shell similarly flattened toward the anterior border.

Surface of shell very smooth, very lustrous, like varnish. Concentric striæ very fine and regular, especially sharp cut at the posterior borders. Growth lamellæ indistinctly bordered. In age, clearly distinguishable by the somewhat projecting borders of the lamellæ. Anterior and lateral borders very thin, sharp-edged, brittle, lying in the plane with the uncovered umbonal borders. Posterior part of the shell scarcely thickened, area more in shape of covering the hollow tip of the beak. Plenrocœlic part of the area somewhat prolonged into the lateral borders. Peduncular groove very broad, somewhat diminished toward the tip of the beak, lying deep but only flatly arched on account of the deficient thickening of the beak. Traces of the pseudo-area rectilinear, converging to the tip of the beak.

Splanchnocœle of the large shell (ventral valve) drawn forth, anterior point of the same bordered in the shape of a bow, and somewhat projecting. Terrace of the thickening of the posterior part of the shell diverging into the brachiocœle, longitudinally palmately striate. Central groove of large shell very flat, posterior part indefinitely bordered, tip drawn out, parallel bordered and anteriorly semicircularly rounded. Corneous processes of the small shell (dorsal valve) strongly receding, sinus indefinitely flattened. Median swelling of small shell strongly developed, beginning in the sinus as a thin, roundish ridge, gradually swelling, reclining beyond the places of attachment of the anterior lateral muscles, and ending shortly before the anterior border in the shape of a pestle. Principal vessels distinguishable in their beginnings, not traced in the brachiocœle. Peripheral canals and accessory vascular furrows in both shells only distinguishable in indistinct traces. Places of attachment of the umbonal muscles large, longitudinally striate, not to be separated from the place of attachment of the peduncular muscle in the large shell. Places of attachment of the central and outside lateral muscles to both sides of the central groove of the large shell, separated from each other and from those of the middle lateral muscles. The latter lie before the semicircularly bordered apex of the central groove. Central muscles (with their advance corresponding to the growth of the animal) leaving behind, in the small shell, a row of traces, which converge into the sinus. Places of attachment of the combined outside and middle lateral muscles, as also those of the transmedian muscles of the small shell, very near the border of the shell.

Observations: The shells of *O. linguliformis* show a different form of outline in their youth than in their age. For the species of the subgenus *Euobolus*, we have demonstrated a proportional growth, and the same also takes place in the species of the other subgenera, as the consideration of the concentric striæ teaches, which marks the stages of age. The form of outline remains the same, except in the very first stages of youth. In *O. linguliformis* the outline of the shell is elliptic until in old age, and then first begins to become subtriangular through the growth lamellæ projecting mostly at the anterior border and anterior lateral borders. Self-evidently, the separation of the substance of the shell takes place also in this stage along the entire border of the shell (including the area), but the lamellæ run, so far as their external part (which forms the surface of the shell) comes into consideration, so sharply into the lateral borders that they do not help to broaden the posterior borders of the shells, but only to thicken them vertically. The outline of the posterior part of the shell, therefore, remains the same, while the anterior part steadily gains in breadth.

In connection with this manner of formation stand the extraordinarily sharply sculptured concentric striæ at the lateral borders of the shell, which are closely crowded against each other.

This characteristically subtriangular outline, which, in connection with the flat arching of the shell, marks the typical form of *O. linguliformis*, is, however, in some specimens given to essential deviations. The beak becomes

broader, and the form of the outline approaches more to the elliptic. At the same time the shell is much more strongly arched. A small shell whose outline deviates only slightly from the typical form is arched much more than the normal specimens. These transition forms point, as we see, toward the variety *solidus*.

The typical form shows two slightly pronounced roundish edges which converge into the tip of the beak and are caused by a lateral flattening of the posterior part of the shell. In like manner the anterior part of the shell is somewhat flattened toward the anterior border. These characters are first plainly perceptible by reflected light, and are much less developed in the described roundish forms. A peculiar correlation also seems to exist between the form of the shell and the strength of the shell. The latter is the slightest in the typical form, increases in the roundish form, and acquires the maximum in *O. lingulaformis solidus*.

The thinness of the shell of the species in question is pronounced, especially in the deficient thickening of the tip of the beak, which in this regard reminds one of the recent lingulas. Here, as well as there, the broad posteriorly diminished peduncular groove is shallow and only indefinitely bordered, and sunk in the area of the large shell. *O. lingulaformis* reminds one, more than all other species of Eichwald's genus, in the formation of the area of the small shell, of the recent *Lingula* with which this part is, to be sure, in a still more pronounced manner, a mere covering of the thin-walled tip of the beak with the corneous area lamellæ.

The configuration of the inner surface of the shell is, in relation to the deficient thickening, quite distinctly developed. In its projecting tip the splanchnocœle of the large shell in some measure resembles the corresponding formation of *Lingula anatina*. On the other hand, the small shell shows the three-lobed form, which is peculiar to the genus *Obolus* and is continued by the aberrant position of the places of attachment of the muscles.

The thickening of the posterior part of the large shell is reduced to a wall-like rim whose pointed upper edge incloses the parietal band. The declivity of this rim into the brachiocœle is quite steep and marked at its middle, circular-formed, projecting part by somewhat diverging longitudinal swellings palmately arranged; the slope into the splanchnocœle is flatter and is lost in the indefinitely bordered central groove, from which only the strongly drawn forth, parallel-bordered, somewhat anteriorly broadened, and rounded-off tip is clearly distinguishable by a slight but sharply bordered depression.

As often mentioned, the places of attachment of the middle lateral muscles, which are removed from the places of attachment of the central muscles, and united to one surface, lie before the tip of the central groove. The places of attachment of the central muscles are oval and lie on both sides of the drawn-out apex of the central groove. They show a coarse transverse striation, which is posteriorly continued farther than the places of attachment, and owes its origin to the gradual advance of the central muscles, whose traces were only partly covered by a slight secretion of lime. A similar condition takes place with the places of attachment of the outside lateral muscles of the large shell, which lie, as with *Schmidtia*, close to the inner sides of the principal vascular canal, far removed from those of the central muscles, and somewhat pushed back. Yet more striking is this succession of exposed traces with the places of attachment of the central muscles of the small shell, in which it may be followed from the inner sides of the corneous processes to the extreme tip of the sinus.

The last-mentioned small shell of the variety *solidus* shows very distinctly—namely, at the right side—the places of attachment of the combined middle and outside lateral muscles as well as those of the transmedian muscles, while the umbonal muscle has left less distinct traces. The first-mentioned places of attachment lie so close to the border of the shell that the pleurocœles are reduced to small, ribbon-shaped striæ. This form of the pleurocœle stands in connection with the previously mentioned law of growth of the shells.

In the large shell the places of attachment of the combined anterior lateral and transmedian muscles, likewise on the right side, are quite distinctly pronounced, while the places of attachment of the divided umbonal muscles and peduncular muscle form a somewhat indefinitely bordered, coherent surface, which is longitudinally striate in the middle.

Very striking to the eye is the strongly developed median swelling of the small shell, which separates the distinctly depressed oval places of attachment of the anterior lateral muscles, and reaches, with its pestle-shaped swelled ends, nearly to the anterior border of the shell; of the circulatory system only the posterior parts of the principal vessels (with the exit out of the splanchnocœle) are unfaillingly distinguishable. The concentric striæ of the small shell are insufficiently covered furrows of separation of the growth lamellæ.

FORMATION AND LOCALITY.^a—**Passage beds** between the Upper Cambrian and the Ordovician: "Glauconite sandstone" at the following localities: (396) at Baltischport, 30 miles (48 km.) west of Reval; (396a) at *Leppiko near Leetz, on the eastern side of the Baltischport peninsula, about 25 miles (40.3 km.) west of Reval*; (396b) at Fall, 15 miles (24 km.) west of Reval; (396c) at the mouth of Föhna Brook, east of Fall, about 15 miles (24 km.) west of Reval; (396d) at Domglint in Reval; and (396f) in the western part of the east Baltic region; all [Mickwitz, 1896, p. 203] in the Government of Esthonia, Russia.

Upper Cambrian: (395) *Obolus* sandstone at Joa, near Jegelecht, 12 miles (19.3 km.) east of Reval, Government of Esthonia, Russia.

^a Localities 395 and 396a are represented in the United States National Museum collections.

LINGULEPIS Hall,^a subgenus of **LINGULELLA**.[Lingula, a tongue; and *ισπίς*, a scale.]

- Lingulepis* HALL, 1863, Sixteenth Ann. Rept. New York State Cab. Nat. Hist., p. 129. (Described as a new genus.)

Genotype.—*Lingula acuminata* Conrad.

Schuchert states in his bibliography [1897, p. 258] that the only essential difference between *Lingulepis* and *Lingulella* is that the ventral beak of the former is often much attenuated. He does not refer to the interior markings of the valves, which have been illustrated as of a peculiar character by Hall [1892c, p. 60]. I quite agree with Schuchert, and I find that, with a fairly good series showing the interiors of both valves, all the essential markings of the vascular system and muscle scars are the same as in *Lingulella*, except as the form of the ventral valve changes the outline of the visceral area. When a shell of *Lingulella* (*Lingulepis*) *acuminata* (Conrad) (Pl. XLII, figs. 1g, 1h) is less attenuate than usual it is almost a good *Lingulella*, both as regards external form and interior markings. It is a fact, however, that many hundreds of specimens with a wide geographic distribution show a persistent form that is readily recognized, and for this reason, and also for convenience of classification, I give *Lingulepis* a subgeneric value.

^a The synonymy for this subgenus does not give a complete record of the various genera under which the species now included in *Lingulepis* were formerly placed; it gives only those references in which the genus is discussed or described. To complete the record the following mere generic references are listed:

The visceral area of *Obolus sinoe* (Pl. XXVI, fig. 2e) is somewhat like that of *Lingulella* (*Lingulepis*) *acuminata* (Pl. XLII, fig. 1g), and also resembles the visceral area of the ventral valve illustrated by Hall [1863, Pl. VI, fig. 15]. The condition of preservation and the original impress made by the different parts of the animal on the shell varies so much in shells of the same species that it is difficult, without a large series of specimens, to decide definitely upon generic or specific characters in the Obolidæ. This is particularly true of *Obolus*, *Lingulella*, and *Lingulepis*.

Of the 14 species and 2 varieties referred to *Lingulepis* from the Cambrian, 1 species occurs in the Lower Cambrian, 9 species and 2 varieties in the Middle Cambrian, and 5 in the Upper Cambrian. One species, *L. (L.) acuminata* (Conrad), is common to the Middle and Upper Cambrian and Ordovician.

For the species that have been referred to *Lingulepis* and which are now referred to other genera, see pages 62-63.

Synonymy of the forms that have been referred to *Lingulepis pinnaformis* (Owen) from the Mississippi Valley, and which are now referred to *Lingulella (Lingulepis) acuminata* (Conrad):

Lingula prima Owen, HALL, 1851, Rept. Geology Lake Superior Land District, by Foster and Whitney, pt. 2, p. 204, Pl. XXIII, figs. 1a-g. (Described and discussed; dorsal valves.)

^a The synonymy for this species is given in two parts; first, the synonymy of the forms that have been referred to the species *acuminata*; second, the synonymy of the forms that have been referred to the species *pinnaformis*. The latter species is now considered to be a synonym of the former.

- Lingula antiqua* Emmons, HALL, 1851, Rept. Geology Lake Superior Land District, by Foster and Whitney, pt. 2, pp. 204-205, Pl. XXIII, figs. 2a-c. (Discussed; ventral valves.)
- Lingula pinnaformis* OWEN, 1852, Rept. Geol. Survey Wisconsin, Iowa, and Minnesota, p. 583, Pl. I B, figs. 4, 6, and 8. (Described.)
- Lingula antiqua* Emmons, HALL, 1862, Rept. Geol. Survey Wisconsin, vol. I, fig. 2, p. 21. (No text reference.)
- Lingula pinnaformis* Owen, HALL, 1862, idem, p. 435, fig. 3, p. 21. (Discussed.)
- Lingula antiqua* Emmons, HAYDEN, 1862, Am. Jour. Sci., 2d ser., vol. 33, p. 73, figs. la-b. (Discussed. It may be that the *Lingula prima* here mentioned by Hayden was based on the dorsal valves of *L. antiqua*.)
- Lingulepis pinnaformis* (Owen), HALL (in part), 1863, Sixteenth Rept. New York State Cab. Nat. Hist., pp. 129-130, Pl. VI, figs. 14-16 (not figs. 12 and 13, referred to *Obolus matinalis*). (Described and discussed.)
- Lingulepis pinniformis* (Owen), MEEK and HAYDEN, 1865, Smithsonian Contrib. Knowl., No. 172, Paleontology Upper Missouri, pp. 2-3, Pl. I, figs. la-b. (Described and discussed.)
- Lingulepis dakotensis* MEEK and HAYDEN, 1865, idem, p. 3. (Name merely proposed in case the species should prove distinct.)
- Lingulepis pinnaformis* (Owen), HALL (in part), 1867, Trans. Albany Inst., vol. 5, p. 107, Pl. I, figs. 14-16 (not figs. 12 and 13, referred to *Obolus matinalis*). (Copy of Hall, 1863, p. 129-130.)
- Lingulepis pinnaformis* (Owen), WHITFIELD, 1880, U. S. Geog. and Geol. Survey Rocky Mtn. Region, Rept. Geology and Resources Black Hills of Dakota, p. 335, Pl. II, figs. 1-4. (Described.)
- Lingulepis dakotensis* Meek and Hayden, WHITFIELD, 1880, idem, pp. 337-338, Pl. II, figs. 10 and 11. (Copies the description given by Meek and Hayden, 1865, p. 2, and discusses species. Figs. 10 and 11 are copied from Meek and Hayden, 1865, Pl. I, figs. 1b and 1a, respectively.)
- Lingulepis pinnaformis* (Owen), WHITFIELD, 1882, Geology of Wisconsin, vol. 4, pp. 169-170, Pl. I, figs. 2 and 3. (Described.)
- Lingulepis pinniformis* (Owen), DWIGHT, 1886, Proc. Am. Assoc. Adv. Sci. for 1885, p. 208. (Mentioned.)
- Lingulepis pinniformis* (Owen), HALL and CLARKE, 1892, Eleventh Ann. Rept. State Geologist New York for 1891, figs. 237 and 238, p. 232; and Pl. I, figs. 16 and 17. (Mentioned. Figs. 237 and 238 are outline drawings of the figures given by Hall, 1863, Pl. VI, figs. 16 and 15, respectively; figs. 16 and 17 (Pl. I) are copied from Hall, 1863, Pl. VI, figs. 16 and 15, respectively.)
- Lingulepis pinniformis* (Owen), HALL and CLARKE, 1892, Forty-fifth Ann. Rept. New York State Museum for 1891, figs. 237 and 238, p. 548. (Mentioned. Figs. 237 and 238 are copied from those on p. 232 of the preceding reference.)
- Lingulepis pinniformis* (Owen), HALL and CLARKE, 1892, Nat. Hist. New York, Paleontology, vol. 8, pt. 1, figs. 22 and 23, p. 60, and Pl. I, figs. 35 and 36. (Mentioned on pp. 60 and 61. Figs. 22 and 23 are outline drawings and figs. 35 and 36 are copies of the figures given by Hall, 1863, Pl. VI, figs. 16 and 15, respectively.)
- Lingulepis pinniformis* (Owen), SCHUCHERT, 1897, Bull. U. S. Geol. Survey No. 87, p. 260. (Questions specific reference.)
- Lingulepis pinniformis* (Owen), GRABAU and SHIMER, 1907, North American Index Fossils, vol. 1, p. 193, fig. 227. (Described. The two figures in figure 227 are copied from Hall, 1863, Pl. VI, figs. 15 and 16.)
- Lingulepis prima* (Hall), GRABAU and SHIMER, 1907, idem, p. 193. (Described, but no figures are given, and it is impossible to tell whether the species should be referred to *Lingulella (Lingulepis) acuminata* or to *Lingulella prima*.)

General form elongate ovate, with the ventral valve subacuminate to acuminate, and the dorsal valve ovate in outline. The outline of the valves varies greatly (Pl. XL). On a single slab of rock from Whitehall, New York, there is a range of variation that unites the slender acuminate form, represented by figure 1c, with forms that are not to be differentiated from *Lingulella acutangula* (Roemer). The range of variation in the dorsal valve is less, but it varies from elongate ovate to nearly round ovate. The convexity of the valves varies with the size and condition of preservation. Those that preserve the natural convexity are rather strongly convex in the dorsal valve, and about one-third less so for the associated ventral valve. The variation in size is very marked, large groups of shells occurring where the average length of the ventral valve is not over 6 to 10 mm. In other localities this increases to 20 mm. with corresponding increase in width.

Surface marked by concentric lines of growth, very fine concentric striæ, and fine radiating striæ. When the outer layer of the shell is exfoliated, the surface is marked by flattened, radiating striæ and concentric lines and striæ of growth. The inner surface is marked by flattened radiating striæ and minute pits or punctæ.

The shells from most localities are relatively thin, but some from the locality at St. Croix Falls show several layers, and those from the sandstones of the Black Hills of South

Dakota are relatively strong and thick. The shell is built up of a thin outer layer and several inner layers or lamellæ that, on the anterior and lateral portions of the shell, are oblique to the outer layer and form a thick, laminated shell very much like that of *Obolus*. Casts of the interior of the ventral valve show a clearly defined area that extends a considerable distance forward along the cardinal slopes. It is divided midway by a strong, rather broad pedicle furrow, and about midway of the very narrow side spaces, by extremely narrow flexure lines. One specimen from the Black Hills shows that the area formed a thin shelf between the pedicle groove and the lateral margins, the undercut extending some little distance beneath it. The area of the dorsal valve is clearly marked in a few specimens; it is relatively short although fairly well extended on the lateral margins.

The cast of the visceral cavity (v) is rarely preserved except in its posterior portion; this is marked by the cast of a median groove, and the path of advance of the central, anterior lateral, and middle lateral muscle scars. Traces of the muscle scars or the anterior portion of the visceral cavity are rarely preserved; thus the heart-shaped pit so often seen in *Lingulella* and *Obolus* is outlined in not over a half dozen specimens out of several hundred casts of the interior. The position and shape of the visceral area varies with the width of the shell. In the long shells it extends far forward, while in the broad shells it scarcely reaches to the center (Pl. XLII, figs. 1e and 1g.) No traces of a median septum have been observed in the ventral valve, but in the dorsal it is shown in the casts as a narrow, clearly defined, sharp depression, extending from between the anterior lateral scars back and between the central muscle scars.

The muscle scars are more or less clearly shown in a number of casts of both valves. The umbonal scar of the ventral valve is divided as in *Obolus*, the pedicle scar (m) (Pl. XLII, fig. 1g) being situated between the two parts (gg). In the dorsal valve the umbonal scar is situated just in front of the area, arching slightly toward the beak. The scars of the central, anterior lateral, and middle lateral muscles are not clearly defined in the ventral valve, owing to their being crowded together in the space on each side of the anterior portion of the visceral cavity.

The central muscle scars of the dorsal valve are of medium size and well defined on a number of casts of the interior of the shell. They are situated a little back of the center of the shell on each side of the median ridge, and their longer axis is slightly inclined outward. The anterior laterals are not well defined in the ventral valve, because they are crowded into a very narrow space. On the dorsal valve they are rarely visible, owing to their very faint impression on the shell. The transmedian scars are distinctly shown on the dorsal valve, but in the ventral valve they have not been differentiated from the anterior laterals.

The markings left on the shell by the vascular system are limited to the main or trunk sinuses on a few casts of the interior (Pl. XLI, fig. 1a, and Pl. XLII, fig. 1e).

Observations.—The type specimens described by Conrad [1839, p. 64] were small, and from an uncertain locality in the "Calciferos sandrock." His associate, Mr. Vanuxem, states [1842, p. 35] that Doctor Eights found a rolled stone containing *L. acuminata*, the surface of the fractured part showing from 60 to 70 valves in an area 2 by 3 inches.

I have collected this species *in situ* in great numbers in Saratoga County, and in the valley of the Hudson near Whitehall, in calcareous sandstones probably equivalent to Conrad's "Calciferos sandrock." The shell corresponds to the description given by Conrad, and occurs in great numbers in partings of the rocks.

In all of the illustrations given of this species from New York, the small, relatively narrow form was figured. The broader and larger form that occurs in the compact, sandy limestone north of Saratoga Springs, and at Beverly, Ontario, does not appear to have been known to the earlier authors.

It was not until 1863 that the Eastern forms so much like those of "*Lingula pinnaformis*" of Wisconsin were illustrated by Billings [1863, p. 102]. Matthew [1895b, Pl. II] illustrated the interior of the ventral and dorsal valves of *L. (L.) acuminata* from Beverly, Ontario. The muscle scars and their markings, as shown in Matthew's diagrammatic figures, vary from those

I have observed, and none of the specimens studied by him showed the area of either the ventral or dorsal valve.

As the result of a comparison of a series of specimens of *L. (L.) acuminata* from the Potsdam sandstone and the base of the "Calceiferous" in Saratoga, Washington, Franklin, and Jefferson counties, New York, and from the same horizon in Ontario, Canada, with a large series of specimens from the "St. Croix sandstone" of Wisconsin, I was led [1897a, p. 404] to conclude that "*Lingula pinnaformis*" Owen was a synonym of *Lingulella (Lingulepis) acuminata* (Conrad), thus making *L. (L.) acuminata* the type of the subgenus *Lingulepis*, the original description of the subgenus being based upon specimens from the "St. Croix sandstone" of Wisconsin.

It is hardly practicable to illustrate all of the varieties of *L. (L.) acuminata* (Conrad) as they occur in widely distributed localities. The shells appear to have varied in size, thickness, convexity, and outline at various localities, and often in the same locality in different layers, probably owing to the character of food supply and the vitality of the individual animals. Very fine specimens of the casts of young shells of the narrow, elongate form occur at Mount Washington, Eau Claire, Wisconsin.

The species ranges from western Vermont, New York, and eastern Canada, westward across the upper Mississippi Valley to the Black Hills of South Dakota, the Bighorn Mountains of Wyoming, and the Rocky Mountains of central Colorado. In the Appalachian region it ranges southward to Tennessee and Alabama, and westward to the Arbuckle and Wichita mountains of Oklahoma, and the Franklin Range near El Paso, Texas. Its vertical range appears to have been from the upper portion of the Middle Cambrian in the Mississippi Valley and the Black Hills to the lower layers of the "Calceiferous" of the Ordovician in New York and Canada.

A number of shells from the Upper Cambrian rocks of Nevada come within the rather wide range of variation of this species. I was at first inclined to place them as a variety, but after extended comparison with a series of specimens from New York and Wisconsin, decided that nothing would be gained by so doing. A few figures on Plate XXXIV, figures 4, 4a-e, illustrate the wide variation in form of the Nevada shell, a variation comparable with that from the typical locality in New York.

A fine series of specimens illustrating the narrow and broad forms has been collected from the limestone in the upper portion of the Reagan sandstone (Upper Cambrian), at the north-west extremity of the Arbuckle Mountains, Oklahoma.

Dwight [1886, p. 208], in speaking of the Upper Cambrian fauna near Poughkeepsie, New York, said:

It will be observed, as has been suggested to me by Whitfield, that the fauna of this locality forms a connecting link between the Potsdam fossils of the Appalachian region and that of the more western States. Thus, the *Lingulella pinnaformis* of Wisconsin and other western localities is here mingled with *Lingulepis minima* and *acuminata* of New York State.

Dwight's remark that the species "*Lingulella pinnaformis*" occurs mingled with "*Lingulepis minima*" and "*L. acuminata*" proves that all the varieties of *Lingulella (Lingulepis) acuminata* occur at the Dutchess County locality.

FORMATION AND LOCALITY.—Ordovician and Upper Cambrian: (338u) Strata from the upper layers of the Potsdam sandstone to the lower portion of the "Calceiferous sandrock" at Chateaugay Falls, Franklin County, New York.

Upper Cambrian: (392e [Billings, 1856, p. 34]) Sandstone on lot 22, ninth concession, township of Bastard; (392d [Billings, 1856, p. 34]) sandstone on lot 11, eleventh concession, township of Lansdowne; and (392b [Matthew, 1895b, p. 258]) sandstone (corresponding to the passage beds above the massive Potsdam sandstone at Chateaugay Falls) at Beverly, township of Bastard; all in the county of Leeds, Ontario, Canada.

(392) Potsdam sandstone at Burgess; (392m) sandstone on the east shore of Missisquoi Bay, 1.5 miles (2.4 km.) south of Phillipsburgh, Province of Quebec; and (392n) sandstone in eastern Canada (exact locality unknown); all in Canada.

(16n) Interformational conglomerates and shales in Adams pasture, 0.5 mile (0.8 km.) west of Main Street, on Lake Street, St. Albans, Franklin County, Vermont.

(76) Arenaceous limestone at Hoyt's quarry, 4 miles (6.4 km.) west of Saratoga Springs, Saratoga County; (76a) arenaceous limestone in a railroad quarry 1 mile (1.6 km.) north of Saratoga Springs, Saratoga County; (109) sandstone 25 feet (7.6 m.) above the Archean, 1.5 miles (2.4 km.) south of Deweys Bridge, on the Champlain Canal, Washington

County; (367k) sandstone at Deweys Bridge, Washington County; (110 and 110a) shaly calcareous sandstone resting on massive layers of Potsdam sandstone, east side of the town of Whitehall, Washington County; (338r [Billings, 1856, p. 34]) Potsdam sandstone at Keeseville, Essex County; (338s [Emmons, 1842, pp. 267 and 268]) *Potsdam sandstone at High Bridge, on Ausable River, Essex County*; (77) sandstone at several horizons in the section below the falls at the high bridge, in Ausable Chasm, Essex County; (111) at the top of the Potsdam sandstone on Marble River, 1 mile (1.6 km.) south of Chateaugay, Franklin County; (338t) Potsdam sandstone in Ausable Chasm, below Keeseville, Essex County; (338w [Hall, 1847, p. 4]) Potsdam sandstone at Hammond, St. Lawrence County; (338j [Hall, 1847, p. 4]) Potsdam sandstone near Alexandria Bay, Jefferson County; (185) sandy layers above the massive Potsdam sandstone one-half mile (0.8 km.) southeast of Redwood, Jefferson County; (185a) sandy layers 20 feet above the massive Potsdam sandstone, east side of Indian View, 3 miles (4.8 km.) south of Theresa, Jefferson County; (367j) sandstone 3 miles (4.8 km.) south of Poughkeepsie, Dutchess County; (108) sandstone 1 mile (1.6 km.) south of Poughkeepsie, Dutchess County; and (367e [Dwight, 1886, p. 205]) shaly limestones 850 feet (259.1 m.) southerly from the southwest corner of the driving park and 2,200 feet (670.6 m.) west of the road leading southerly from the same, about 1 mile (1.6 km.) southwest of Vassar College, near Poughkeepsie, Dutchess County; all in New York.

(92b) Limestone on Buffalo Creek, 2 miles (3.2 km.) southeast of Buffalo Mills, Rockbridge County, Virginia.

(105) Limestone in Knox dolomite, at Bishops Mill, Hancock County; and (107o) limestones and shales at the base of the Knox dolomite, west of the top of Copper Ridge, near the Southern Railway cut, about 10 miles (16.1 km.) northwest of Knoxville [Keith 1896b, areal geology sheet], Knox County; both in Tennessee.

(79 and 79b) "St. Croix sandstone" near Hudson, St. Croix County; (82 and 82s) "St. Croix sandstone" on the bank of St. Croix River, St. Croix Falls, Polk County; (328h) silicocalcareous layers of Flb of Owen, at the falls of the St. Croix, Polk County; (97a) "St. Croix sandstone" near Winfield, Jefferson County; (98) "St. Croix sandstone" near Eau Claire, Eau Claire County; and (99a) "St. Croix sandstone" near Pilot Knob, Adams County; all in Wisconsin.

(330 [Hall, 1851, p. 204]) Sandstone on Taquamenon Bay, Chippewa County; (330b) sandstone at Iron Mountain, Dickinson County; and (330a [Hall, 1851, p. 204]) sandstone on Escanaba River; all in northern Michigan.

(339h [Hall, 1863, p. 130]) "St. Croix sandstone" near the mouth of the Minneiska (Miniska) River, near the line between Wabasha and Winona counties; and (97b) "St. Croix sandstone" below the greensand bed and about 25 feet above St. Croix River at Franconia, Chisago County; both in Minnesota.

(353b) Sandstone just beneath the *Ophileta* zone, south end of the Franklin Range, El Paso County, Texas.

(360g) Shaly sandstone on Trout Creek, 1 mile (1.6 km.) below Manitou Park, El Paso County, Colorado.

(54d) About 1,050 feet (320 m.) above the Middle Cambrian and 175 feet (53.3 m.) below the top of the Upper Cambrian in the lower part of the limestone forming 1 of the St. Charles formation [Walcott, 1908f, p. 192]; and (54g) just above the Middle Cambrian, near the base of the bedded light-gray sandstone forming 4 of the St. Charles formation [Walcott, 1908f, p. 193]; both in Blacksmith Fork Canyon about 10 miles (16.1 km.) east of Hyrum, Cache County, Utah.

(7x and 7y) Limestone of the Emigrant formation [Turner, 1902, p. 265], about 2.5 miles (4 km.) southeast of Emigrant Pass; and (7z) limestone of the Emigrant formation [Turner, 1902, p. 265], about 3 miles (4.8 km.) southeast of Emigrant Pass; both in the Silver Peak quadrangle (U. S. Geol. Survey), Esmeralda County, Nevada.

(9q) About 10 feet (3 m.) above the porphyry contact and 90 feet (27.4 m.) below the Arbuckle limestone in limestone of the Reagan sandstone, middle of west half of sec. 2, T. 4 N., R. 13 W., about 15 miles (24.2 km.) northwest of Fort Sill, Comanche County; (9s) about 85 feet (26 m.) below the Arbuckle limestone in the limestone of the Reagan sandstone, near middle of west half of sec. 13, T. 4 N., R. 13 W., 13 miles (20.8 km.) northwest of Fort Sill, Comanche County; (9v) limestone of the Reagan sandstone, about 250 feet (76 m.) below the Arbuckle limestone, SW. $\frac{1}{4}$ sec. 17, T. 4 N., R. 12 W., about 11 miles (17.7 km.) northwest of Fort Sill, Comanche County; (12n) limestone of the Reagan sandstone (in the section 7 miles (11.2 km.) north of Springer this horizon is about 240 feet (73 m.) above the porphyry contact and 40 feet (12 m.) below the Arbuckle limestone), NW. $\frac{1}{4}$ sec. 1, T. 2 S., R. 1 E., Ardmore quadrangle (U. S. Geol. Survey), Carter County; and (12p) about 225 feet (69 m.) above the igneous rocks in the limestone of the Reagan sandstone, at the northwest extremity of the Arbuckle Mountains, about 4 miles (6.4 km.) east of Homer, Carter County; all in Oklahoma.

(14b) Limestone on Cold Creek at north end of gorge opposite the north end of Sponge Mountain, 2 miles (3.2 km.) south of the San Saba County line in Llano County; (14r) sandstone in the lower part of the beds exposed on Colorado River, 3 miles (4.8 km.) south of the northeast corner of Llano County; (69) limestone near Honey Creek, Burnet County; and (70) limestone near Morgans Creek, Burnet County; all in Texas.

Middle Cambrian: (328e) "St. Croix sandstone" at St. Croix Falls, Polk County; and (79x) "St. Croix sandstone" near the flour mill on Beaver Creek, north of Galesville, Trempealeau County; both in Wisconsin.

(84) "St. Croix sandstone" at Dresbach, opposite the mouth of Black River, Winona County; (84s) "St. Croix sandstone" near Dakota, Winona County; (339j) sandstone between the lowest blue shale and the reddish calcareous beds above, at Taylors Falls, Chisago County; and (339k) sandstone near Winona, Winona County; all in Minnesota.

(89) Limestone in Murphrees Valley, Blount County, Alabama.

(374d) Shale 2 miles (3.2 km.) north of Rotherwood; and (124a) shale (Nolichucky?) overlying the limestone which rests on the Rogersville shale, on Big Creek, southeast of Harlan Knob, 4 miles (6.4 km.) northeast of Rogersville [Keith, 1905, p. 4, and areal geology sheet]; both in Hawkins County, Tennessee.

(355) Sandstones on Red Canyon Creek, southwest side of Black Hills; (355d) sandstone in the Black Hills; (164) sandstone in the Deadwood formation in the cliffs on the east side of the valley near Deadwood, Black Hills; (167) sandstone beneath limestone and resting on the pre-Cambrian in a bluff 9 miles (14.4 km.) west of Custer, Black Hills; and (355b) sandstone in the Deadwood formation on Castle Creek, west side of Black Hills; all in South Dakota.

(171 and 171a) Sandstone in Big Goose Creek Canyon, Bighorn Mountains, west of Sheridan, Sheridan County; (302m) middle of shale above lower sandstone on Billy Creek, in the Bighorn Mountains, Sheridan County; and (340c) dark-red sandstone near the base of the Cambrian at Rawlins, Carbon County; all in Wyoming.

LINGULELLA (LINGULEPIS) ACUMINATA MEEKI (Walcott).

Plate XLI, figures 2, 2a.

Lingulepis meeki WALCOTT, 1897, Am. Jour. Sci., 4th ser., vol. 3, p. 405. (Described and discussed as below as a new species.)

Obolus (Lingulepis) acuminatus meeki WALCOTT, 1899, Mon. U. S. Geol. Survey, vol. 32, pt. 2, p. 444, Pl. LX, figs. 1 and 1a. (Text copied from preceding reference. The specimens represented by figs. 1 and 1a are redrawn in this monograph, Pl. XLI, figs. 2 and 2a, respectively.)

Obolus (Lingulepis) acuminata weeksi WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 333. (Merely used for *Obolus (Lingulepis) acuminata meeki* by mistake in discussion of "*Obolus (Lingulepis) eros*.")

Shell small, attenuate, marked by rather strong concentric lines and striæ of growth, and interrupted, irregular, radiating striæ.

Ventral valve narrow, elongate, beak acuminate, rostral slopes long, nearly straight, passing gradually into the curvature of the anterolateral margins, and posteriorly meeting at a very acute angle; front strongly rounded. Length of valve, 8 mm.; width, 3.5 mm., the widest portion being near the anterior extremity. Beak slightly upcurved, the longitudinal median line straight or even slightly concave from the apex of the beak to the middle, where it begins to slope gently to the frontal margin; transverse curvature very slight anteriorly, more convex than the beak.

Dorsal valve more convex than the ventral, linguliform; beak depressed, bluntly rounded, curving evenly and gradually to the semitruncate anterior margin.

Observations.—The interior markings of this shell have not been ascertained, but the external characters are such as to make a reference to the subgenus *Lingulepis* more than probably correct. The flat, acute-acuminate ventral valve with its elevated or retrorse beak, which is not covered by the smaller dorsal valve, is characteristic of *Lingulepis*.

There is a form from Texas, probably identical with *Lingulella perattenuata* (Whitfield) that might be mistaken for this variety, but it is an undoubted *Lingulella* and does not show the external characteristics of *Lingulepis*. A comparison of *Lingulella (Lingulepis) acuminata meeki* with the young and narrow specimens of *L. (L.) acuminata* (Conrad) shows it to vary from that species, the posterior rostral slopes of *L. (L.) acuminata* possessing a peculiar incurving which is not shown in *L. (L.) acuminata meeki*.

After the publication of "*Lingulepis meeki*" [Walcott, 1897, p. 405] shells were collected from the north end of the Teton Range, which showed that that form was very closely related to *L. (L.) acuminata*. As all the Teton Range shells were quite small and the majority had the characters of "*Lingulepis meeki*," the latter was reduced to a variety of *L. (L.) acuminata* [Walcott, 1899, Pl. LX, figs. 1 and 1a], and the Teton shells were included with those from the Gallatin Range.

The varietal name was given in honor of Dr. F. B. Meek.

FORMATION AND LOCALITY.—Middle Cambrian: (302b) Limestones near Crowfoot Ridge, Gallatin quadrangle (U. S. Geol. Survey), Yellowstone National Park; and (4e) limestones about 950 feet (289.6 m.) above the unconformable base of the Cambrian in the divide at the head of Jackson Creek (locally known as Sheep Creek), a creek flowing into Jackson Lake about 0.5 mile (0.8 km.) south of its northwest corner, Teton Mountains, Grand Teton quadrangle (U. S. Geol. Survey), Uinta County; both in Wyoming.

(4h) About 375 feet (114.3 m.) above the base of the Cambrian in limestone interbedded in the Flathead shales of Peale [1893, p. 21], 1 mile (1.6 km.) north of the junction of East Gallatin and West Gallatin (Gallatin) rivers, 4 miles (6.4 km.) east-northeast of Logan, Threeforks quadrangle (U. S. Geol. Survey), Gallatin County, Montana.

LINGULELLA (LINGULEPIS) ACUMINATA SEQUENS Walcott.

Text figures 46A-B.

Glossina acuminata HALL and CLARKE [not CONRAD], 1892, Eleventh Ann. Rept. State Geologist New York for 1891, Pl. I, figs. 10 and 11. (No text reference.)

Lingula (Glossina) acuminata HALL and CLARKE [not (CONRAD)], 1892, Nat. Hist. New York, Paleontology, vol. 8, pt. 1, Pl. I, figs. 1 and 2. (No text reference. Figs. 1 and 2 are copied from Hall and Clarke, 1892a, Pl. I, figs. 10 and 11, respectively.)

Lingulella (Lingulepis) acuminata sequens WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 3, p. 72, Pl. VIII, fig. 4. (Characterized and discussed as a new variety. Fig. 4 is copied in this monograph as fig. 46A.)

This variety differs from *Lingulella (Lingulepis) acuminata* (Conrad) in being somewhat less attenuate in its ventral valve, and in having the cardinal slope of the ventral valve straight, instead of gently incurved.

It occurs at a slightly higher geologic horizon than *L. (L.) acuminata*, and appears to be a form derived from that species.

Judging from Hall and Clarke's illustrations [1892a, Pl. I, figs. 10 and 11] they had representatives of this variety of *Lingulella (Lingulepis) acuminata* and mistook them for the form illustrated by Hall [1847, p. 9] as *Lingula acuminata*. That figure represents a typical form of *L. (L.) acuminata*, and is not the variety illustrated by Hall and Clarke in 1892.

The specimens illustrated by Hall and Clarke are given as from Saratoga County, New York, "Calciferous sandstone." The specimens which I have taken as typical of this variety are from Division A of the Beekmantown limestone.

This form owes its varietal name to the fact that it is a later representative of the species.

FORMATION AND LOCALITY.—Ordovician: (367c) Beekmantown limestone, Division A; quarry near the northwest suburb of Ticonderoga, Essex County, New York.

LINGULELLA (LINGULEPIS) EROS (Walcott).

Plate XXXIX, figures 9 and 9a.

Obolus (Lingulepis) eros WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 333. (Described and discussed as below as a new species.)

Ventral valve elongate with rostral slopes gradually converging so as to form an acuminate beak. Surface marked by fine concentric lines of growth and very fine, somewhat irregular, concentric striæ. Rather large scattered punctæ occur on the interior surface.

This species is represented by fragments and two broken ventral valves; these indicate a length for the ventral valve of from 7 to 10 mm. It is allied to *Lingulella (Lingulepis) acuminata meeki*^a (Walcott) of the Middle Cambrian fauna of the Teton mountains of Wyoming.

FORMATION AND LOCALITY.—Middle Cambrian: (C7) Lower limestone member of the Kiulung group [Blackwelder, 1907a, pp. 37 and 39 (last list of fossils), and fig. 8a (bed 33), p. 29], 2.2 miles (3.5 km.) southwest of Yenchuang, Sintai district, Shantung, China.

LINGUELLA (LINGULEPIS) EXIGUA (Matthew).

Plate XXXIII, figures 4, 4a; Plate XLIII, figures 1, 1a-z.

Obolus (Lingulepis) gregwa WALCOTT (in part) [not (MATTHEW)], 1901, Proc. U. S. Nat. Mus., vol. 23, pp. 692-694. (Described and discussed almost as on pp. 552-553, with the exception of the notes under "Observations," which have been rewritten in this monograph. The following species were included in this reference: *Lingulella (Lingulepis) exigua*, *L. (L.) gregwa*, *Lingulella tumida*, and *L. atava*.)

FIGURE 46.—*Lingulella (Lingulepis) acuminata sequens* Walcott. A, Ventral valve showing nearly straight lateral slopes (U. S. Nat. Mus. Cat. No. 53675a). B, Dorsal valve (U. S. Nat. Mus. Cat. No. 53675b).

The specimens represented are from Locality 367c near Ticonderoga, New York. Fig. 46A is copied from Walcott [1908d, Pl. VIII, fig. 4]. It represents the type specimen.

^a Written "weeksi" in the original description [Walcott, 1905a, p. 333] through mistake.

Lingulepis starri var. MATTHEW, 1903, Geol. Survey Canada, Rept. Cambrian Rocks Cape Breton, pp. 193-197, Pl. XIV, figs. 2a-c. (Gives an essential copy (rearranged) of the description given by Walcott, 1901, pp. 692-694, and describes and discusses the specimens referred by Walcott to *Obolus (Lingulepis) gregwa* as belonging to an undetermined variety of Matthew's "*Lingulepis starri*.")

Lingulepis starri exigua MATTHEW, 1903, idem, pp. 197-198, Pl. XIV, figs. 3a-d. (Described and discussed as a new variety.)

General form elongate ovate with the ventral valve acuminate and the dorsal valve ovate triangular in outline. The outline of the valves varies, as shown by the series of figures on Plate XLIII and by many other specimens not illustrated. The convexity of the valves varies with the condition of the preservation, those from the sandstone being rather strongly convex, while those in the shale are very much compressed. On the dorsal valve of the youngest shells there is a marked and rather broad, shallow sinus extending from the umbo to the front where it flattens out.

One of the largest ventral valves has a length of 21 mm., with a width of 18 mm. A dorsal valve 16 mm. in width has the same length; other examples are a little wider than long.

Surface of the shell marked by concentric striæ and undulations of growth, over which there is a series of very fine, elevated, sharply undulating and inosculating lines that form a minute irregular network over the surface, very much like that of *Lingulella (Lingulepis) gregwa* (Matthew), except that the irregular lines are very much finer on the latter. Where the lines are strongly elevated the effect is that of a minutely granulose surface. In some examples the surface suggests an incrusting or scabrous outer layer of shell covered with minute points. When the thin outer layer of the shell is exfoliated the surface of the various bright, shiny, inner layers is minutely granulose, in addition to the flattened, radiating striæ and concentric lines of growth. The interior surface of both valves is often marked by concentric rows of strong pits or punctæ very much as in *Lingulella davisi* (McCoy) (Pl. XXXI, fig. 6g). In some specimens the lines of punctæ extend over the surface of the visceral cavity so as to obscure the vascular markings and muscle scars. In some examples only a few scattered punctæ occur, while in others they are present over nearly the entire surface. The small shells are thin, but the larger ones are built up of a very thin outer layer and several inner layers or lamellæ that are more or less oblique to the outer surface, especially over the anterior and lateral portions of the shell.

The plane of the cardinal area of the ventral valve is nearly coincident, near its edges, with the edge of the shell. The area is long and extends well forward on the cardinal slope. It is divided midway by a narrow, rounded, deep pedicle furrow, and about half way between the pedicle furrow and the lateral margins by an unusually well-defined flexure line which is in line with the main vascular furrows of the interior of the valves; fine striæ of growth cross the area and arch around the pedicle furrow parallel to the base of the area. There is practically no undercut beneath the area except near the flexure line at the frontal margin of the area. The area of the dorsal valve is short, narrow, and crossed by fine lines of growth parallel to its base.

The cast of the visceral cavity in the ventral valve shows it to have been relatively small and usually confined to the posterior half of the shell, although in some shells it extends past the center (Pl. XLIII, fig. 1q). There are no traces of a median septum in the ventral valve; in the dorsal valve, at the bottom of the groove between the central muscle scars, there is a slightly elevated median line that extends forward to the anterior margin of the visceral cavity beyond the anterior lateral muscle scars. The visceral cavity of the dorsal valve usually extends forward to about the center of the valve, but in a series of specimens collected in 1903 a number of interior casts show the front of the visceral area varying in position from back of the center to nearly the frontal margin of the shell; it varies in width and outline very much as the shells vary, being wide in broad shells and narrow in elongate forms.

The markings left on the shell by the vascular system are very strong and beautifully preserved in some portions. The direction and size of the main sinuses are well shown by the illustrations; in some shells there is a double groove with a slight ridge between; in others the

ridge is large, only a trace of an outer groove remaining; in some young shells the groove is broad and shallow; in all shells the large size of the main vessels is shown by the broad, strong grooves or ridges left on the shell. It frequently happens that the lines of sharply defined pits on the lines of growth deeply indent the grooves and rounded ridges left by the main vessels and mark them off into sections. The interior and lateral vessels left narrow but strong grooves or ridges on the shell, which, however, are usually obscured by the strong pitting of the surface. The parietal scar surrounds the visceral cavity in each valve, crosses the course of the main vascular vessels, and comes back around the spaces occupied by the muscle scars, terminating at the edge of the area at the flexure line in the ventral valve; termination unknown on the dorsal valve.

Some of the muscle scars are finely shown in the dorsal valve and fairly well in the ventral. The umbonal scar of the ventral valve is divided, the pedicle scar being situated between the two parts. In the dorsal valve the umbonal scar is close to the area, and extends nearly as far each side of the median line as the length of the area.

The scars of the central muscles in the ventral valve are crowded in with the middle and outside laterals within the trapezoidal space (c, Pl. XLIII, figs. 1q and 1s). In the dorsal valve they are located on a low ridge each side of a central, longitudinal median depression; they are elongate oval in outline, their major axis being subparallel to the median line of the shell; fine longitudinal lines cross the scars in the best preserved specimens; the ridge on which the central scars occur varies in strength, but it appears to be present in all adult shells; it narrows gradually posteriorly and rather rapidly to the inner side of the anterior lateral muscle scars. The anterior laterals of the ventral valve are placed well back on the narrow space between the edge of the area and the main vascular sinus; they are elongate and rather large; in the dorsal valve they are elongate with the major axis inclining toward the median line (Pl. XLIII, figs. 1r and 1y). The middle and outside laterals are situated in the trapezoidal area (c) of the ventral valve, but neither is clearly separable from the other or from the central scars. In the dorsal valve the position of the middle and outside laterals is shown, but not their form or size. The transmedian scars in the ventral valve are seen just back of the anterior laterals, but they have not been observed in the dorsal valve owing to the imperfections of the shell.

Observations.—This is one of the most interesting species of *Lingulepis* I have known. In its coarsely pitted inner surface it recalls *Lingulella davisi* (McCoy) (Pl. XXXI) of England, and *Obolus willisi* (Walcott) (Pl. XXIII) of the southern Appalachians. The elongate ventral valve is like that of *Lingulella (Lingulepis) acuminata* (Conrad), while the interior scars and markings are those of *Obolus*. With *L. (L.) gregwa* (Matthew) and *L. (L.) starri* (Matthew) it is the Atlantic coast representative of *L. (L.) acuminata* which is so abundant in the Middle Cambrian of the Upper Mississippi Valley, and in the passage beds between the Cambrian and the Ordovician in the region adjoining the Adirondack Mountains of New York. It differs from *L. (L.) acuminata* in its surface characters.

The shells embedded in the fine-grained shales are all flattened and more or less distorted by compression, while those in the sandy layers interbedded in the shales retain their original convexity, although frequently distorted and fractured by movement of the matrix. The fracturing of the brittle, mineralized shell is beautifully illustrated by Plate XXXIII, figure 4a, which represents the siliceous fillings of the fractures, the shell substance having been dissolved with acid.

Typical specimens of *Lingulella (Lingulepis) exigua* have narrow, elongate ventral valves and broadly oval dorsal valves. I was at first strongly inclined to separate the broad, thick shells as a distinct species, but on finding a series of connecting forms and observing that the surface and interior markings were similar, I decided to unite them. The shells vary materially in their external aspect in the different layers of siliceous rock, but when the shell substance is removed by acid it is found that their interior and exterior characters are the same. The typical forms of *L. (L.) exigua* are represented in Plate XLIII, by figures 1, 1a–b, 1d, 1g–j, and the variations

by figures 1f, 1o-s. With growth in size and age the shell increases in thickness notably over the posterior portions.

In some notes [1901, p. 692] on "*Lingulepis gregwa*" (Matthew), I identified this shell as "*Obolus (Lingulepis) gregwa*." It is closely related to it but differs in the surface characters. The exterior shell of *Lingulella (Lingulepis) gregwa* is marked by fine, irregular, elevated, and sometimes inosculating ridges that have a row of minute tubercles on them that give a beaded appearance to each ridge. The surface of the shell of *L. (L.) exigua* has a much more minutely granulose surface formed by very irregular, inosculating, elevated lines or ridges, much like that of *L. (L.) roberti* (Matthew).

Matthew [1903, p. 193] refers this form to "*Lingulepis starri* var." With the types of *starri* as a basis of comparison I find that the type of surface of *starri* is as stated by Matthew [1891, p. 147]: "Each valve is ornamented by numerous, concentric furrows, closely set, about 12 to 15 to a millimeter." I find 8 to 10 on one of the typical specimens. This surface is quite unlike the surface of *L. (L.) exigua* which is as described above. When the thin outer layer is exfoliated the concentric striæ and ridges of growth are like the surface of *starri*, but the outer surface is roughened ("granulated," Matthew) in a manner unlike the surface of *L. (L.) exigua*. It has the appearance under a strong magnifier of a surface produced by fine points distributed over an incrusting layer of shell.

FORMATION AND LOCALITY.—Upper Cambrian: (3n) Thin-bedded sandstone on Salmon River, Gillis Hill, 13 miles (20.9 km.) south of Marion Bridge, eastern Cape Breton, Nova Scotia.

Middle Cambrian: (3i) Compact, fine-grained, thin-bedded, gray sandstone of the *Paradoxides* zone [horizon of Division C2b, Matthew, 1903, p. 195], on McLean Brook, 1 mile (1.6 km.) east of McCodrum Brook and 1.5 miles (2.4 km.) west of Marion Bridge; (10s and 10t) sandstone on McLean Brook, near Marion Bridge; (307f [Matthew, 1903, p. 198]) shale of Division C2a on McLean Brook, Mira River; (307g [Matthew, 1903, pp. 195 and 198]) shales of Division C2b on McLean Brook, Mira River; (13r) sandstone of the "Johannian" Division of Matthew's section on Gillis Brook, East Bay, east of Bras d'Or Lake; and (11z) sandstone on Big Ridge, 2 miles (3.2 km.) south of Marion Bridge, on the canal of John McDougald; all in eastern Cape Breton, Nova Scotia.

LINGULELLA (LINGULEPIS) GREGWA (Matthew).

Plate XLIV, figures 1, 1a-p.

Lingulella gregwa MATTHEW, 1899, Bull. Nat. Hist. Soc. New Brunswick, vol. 4, pp. 199-200, Pl. I, figs. 1a-f. (Described and discussed as a new species.)

Obolus (Lingulepis) gregwa WALCOTT (in part), 1901, Proc. U. S. Nat. Mus., vol. 23, pp. 692-694. (The following species were included under *Lingulella (Lingulepis) gregwa* in this reference; *Lingulella (Lingulepis) exigua*, *L. (L.) gregwa*, *Lingulella tumida*, and *L. atava*. The specimens upon which the description was based are now referred to *Lingulella (Lingulepis) exigua*.)

Lingulepis gregwa MATTHEW, 1903, Geol. Survey Canada, Rept. Cambrian Rocks Cape Breton, pp. 56-57. (Notes on orientation of shells.)

Lingulepis gregwa MATTHEW, 1903, idem, pp. 126-131, Pl. IX, figs. 3a-f. (Described and discussed. Figs. 3a-f are copied from Matthew, 1899, Pl. I, figs. 1a-f.)

The description of *Lingulella (Lingulepis) exigua* (Matthew) applies very closely to this species, with the exception of the surface characters and details of outline, and the interior markings of the valves. As a whole, the ventral valve of *L. (L.) gregwa* is less acuminate, and the outline of the dorsal valve is more rounded posteriorly. A comparison of the series of illustrations of the two species fully exhibits the differences referred to. The exterior surface of the shell of *L. (L.) gregwa* is marked by a few, strong, concentric lines of growth, and numerous fine, concentric, irregular, often inosculating ridges having a row of minute tubercles on them that gives a beaded appearance to each ridge. This appearance is unmistakable when the outer shell is at all well preserved. There are also indications of very fine radiating ridges, irregularly dispersed over the surface of the shell. When the thin, highly ornamented outer layer is exfoliated the various lamellæ of the shell show very fine, radiating striæ, and a few concentric lines of growth. The interior of the shell has rather large scattered punctæ, and occasionally a specimen shows the punctæ gathered in concentric lines. The shell is built up of a thin outer layer and several inner layers, or lamellæ, that are more or less oblique to the

outer surface, especially over the anterior and lateral portions of the shell, where they are much more numerous. In many specimens the shell substance has been replaced by calcite.

Interiors of the ventral valve show considerable difference in the position of the main vascular sinuses. They are usually well out toward the sides. In the dorsal valve the main vascular sinuses are widely separated, and the visceral area is well extended toward the front.

Observations.—When studying the collections made by S. Ward Loper on McLean Brook in 1900, I identified the shells now placed under *Lingulella (Lingulepis) exigua* as "*Obolus (Lingulepis) gregwa*." But at that time I had only the somewhat imperfect material in Matthew's collection from Dugald Brook for the purposes of comparison. With a large series of well-preserved specimens collected on Dugald Brook in 1901 by Loper, the fact that the two species had been confused became at once apparent. *Lingulella (Lingulepis) gregwa* is found in great numbers at a lower stratigraphic horizon beneath the *Paradoxides* zone, while *L. (L.) exigua* occurs at the summit of the Middle Cambrian fauna in association with *Paradoxides*. Both species have strong points of resemblance to *L. (L.) acuminata* (Conrad) and both, in their younger stages, depart to such an extent from the typical forms of the adult shell that they might be considered a distinct species if found at another locality or stratigraphic horizon.

The specific name is derived from Gregwa Brook, on which specimens of the species occur.

FORMATION AND LOCALITY.—**Middle Cambrian:** (10p) Sandstone just below the waterfall in Division E2b of Matthew's [1903, p. 21] Etcheminian, on Dugald Brook, Indian River; (10p') sandstone one-fourth mile (0.4 km.) from lower bridge, on Gregwa Brook, Indian River; (10p'') sandstone on the small brook on the hill between the bridge over Indian River and McPhees Brook; (13t'') sandstones of Divisions E1c and E1d of Matthew's [1903, p. 21] Etcheminian, on Dugald Brook, Indian River; (344e [Matthew, 1903, p. 78]) shales of Division E1d of Matthew's [1903, pp. 28 and 29] Etcheminian, on Boundary Brook, eastern side of the Escasonie Indian Reservation; (344k^a [Matthew, 1903, p. 77]) sandstones of Division E1b of Matthew's [1903, p. 21] Etcheminian, on Dugald Brook, Indian River; (344m [Matthew, 1903, p. 78]) sandy shales of Division E1d of Matthew's [1903, p. 21] Etcheminian, on Dugald Brook, Indian River; and (344n [Matthew, 1903, p. 33]) shales in the gorge at the old mill on McCodrum Brook, Mira River; all in eastern Cape Breton, Nova Scotia.

LINGULELLA (LINGULEPIS) GREGWA ROBUSTA (Matthew).

Lingulepis gregwa robusta MATTHEW, 1903, Geol. Survey Canada, Rept. Cambrian Rocks Cape Breton, p. 57. (Notes on orientation of shells.)

Lingulepis gregwa robusta Matthew, 1903, idem, p. 131. (Characterized as a new variety.)

Matthew separates a form with a thicker shell and straighter cardinal margins as the variety *robusta*. My impression is that these characters are so largely the result of the condition of preservation of the specimens in the matrix that the variety has very little value.

FORMATION AND LOCALITY.—**Middle Cambrian:** (10p) Sandstone just below the waterfall in Division E2b of Matthew's [1903, p. 21] Etcheminian, on Dugald Brook, Indian River; (10p') sandstone one-fourth mile (0.4 km.) from lower bridge, on Gregwa Brook, Indian River; (10p'') sandstone on the small brook on the hill between the bridge over Indian River and McPhees Brook; (13t'') sandstones of Divisions E1c and E1d of Matthew's [1903, p. 21] Etcheminian, on Dugald Brook, Indian River; (344h [Matthew, 1903, p. 79]) sandy layers in the shales of Division E1e of Matthew's [1903, p. 21] Etcheminian, on Dugald Brook, Indian River; and (344m [Matthew, 1903, p. 78]) sandy shales of Division E1d of Matthew's [1903, p. 21] Etcheminian, on Dugald Brook, Indian River; all in eastern Cape Breton, Nova Scotia.

LINGULELLA (LINGULEPIS) LONGINERVIS (Matthew).

Plate XLIV, figures 2, 2a-g.

Lingulepis longinervis MATTHEW, 1903, Geol. Survey Canada, Rept. Cambrian Rocks Cape Breton, pp. 133-135, Pl.

VII, figs. 6a-g. (Described and discussed as a new species. The specimen represented by figure 6f is redrawn in this monograph, Pl. XLIV, fig. 2e.)

This species differs from *Lingulella (Lingulepis) gregwa* (Matthew) in having the sides of the ventral valve extended in a nearly straight line beyond the center of the valve. Some of Matthew's specimens have a concentrically striated surface with only a trace of the characteristic surface of *L. (L.) gregwa*. Others show more of the ornamented surface, and in specimens

^a Doubtfully identified from this locality.

collected by S. Ward Loper from the same beds from which the types of *L. (L.) longinervis* came, the surface is indistinguishable from that of *L. (L.) gregwa*.

Matthew [1903, p. 134] considers the long, large "visceral callus" of the dorsal valve as the most prominent characteristic of this form. I find in *L. (L.) gregwa* (Matthew) and *L. (L.) exigua* (Matthew) that the visceral area in many specimens extends nearly to the front of the dorsal valve and that the length and strength of the visceral area in both ventral and dorsal valves of *Lingulepis* are not usually characters to be depended upon as criteria for specific determinations. The position assigned to the central and anterolateral muscle scars by Matthew [1903, Pl. VII, figs. 6e and 6f] appears to be theoretical, as a most careful study of the typical specimens fails to locate them as indicated in the figures. In fact, the specimens are too poorly preserved to indicate clearly where the scars are. Fine casts of the interior collected by Loper show the scars named farther toward the central portion of the shell.

Lingulella (Lingulepis) longinervis differs from *L. (L.) exigua* (Matthew) in its less attenuate ventral valve and less robust character in both size and thickness of shell.

The specimens collected by Matthew are small and do not show the variation that exists in the collection made by Loper. In a layer of reddish brown sandstone Loper found a great number of shells varying in size and form from those similar to Matthew's types to shells nearly twice as large. In a layer of hard gray sandstone, 5 feet above, all the specimens are similar in size and form to those collected by Matthew. *Lingulella triparilis* (Matthew) occupies a position intermediate in form between *L. (L.) gregwa* (Matthew) and *L. (L.) longinervis*, and the surface characters of the three species are essentially of the same type.

FORMATION AND LOCALITY.—Middle Cambrian: (372f) shales of unknown stratigraphic position; (13d'') sandstones 10 feet (3 m.) below Division E2a; (13g) sandstones 10 feet (3 m.) above Division E2a; (13f) sandstone 20 feet (6 m.) above Division E2a; (13p and 13p') sandstones 40 to 45 feet (12.2 to 13.6 m.) above Division E2a; (13d) sandstones opposite the third waterfall in Dugald Brook, between Divisions E2a and E2b; (10p) sandstones just below the waterfall, in Division E2b; (344o [Matthew, 1903, p. 134]) sandstones of Division E2b; and (131) shaly sandstones of Division E3a; all in Matthew's [1903, p. 21] Etcheminian, on Dugald Brook, Indian River, eastern Cape Breton, Nova Scotia.

(10p') Sandstone one-fourth mile (0.4 km.) from lower bridge, on Gregwa Brook, Indian River; and (10p'') sandstone on the small brook on the hill between the bridge over Indian River and McPhees Brook; both in eastern Cape Breton, Nova Scotia.

LINGULELLA (LINGULEPIS) PUMILA (Matthew.)

Plate XLV, figures 3, 3a.

Lingulepis pumila MATTHEW, 1903, Geol. Survey Canada, Rept. Cambrian Rocks Cape Breton, p. 75, Pl. VII, figs. 5a and 5b. (Described as a new species. The specimens represented by figs. 5a and 5b are redrawn in this monograph, Pl. XLV, figs. 3 and 3a, respectively.)

This species differs from *Lingulella triparilis* (Matthew) and *Lingulella (Lingulepis) gregwa* (Matthew) in having a more attenuate ventral valve. In this respect it resembles the narrow forms of *L. (L.) longinervis* (Matthew). The material is poor, so that only the general form can be used to characterize it. One dorsal valve shows that the shell was thick, very much as in *L. (L.) exigua* (Matthew). The surface of exfoliated shells is nearly smooth. Matthew [1903, p. 75] describes the outer surface as consisting of irregular concentric ridges, about six in the space of a millimeter.

FORMATION AND LOCALITY.—Middle Cambrian: (344f [Matthew, 1903, p. 72]) Shales in the Coldbrook terrane of Matthew, on Dugald Brook, Indian River, eastern Cape Breton, Nova Scotia.

Specimens that are somewhat doubtfully referred to this species occur at the following locality:

Middle Cambrian: (13k) Shales of Matthew's [1903, p. 15] Coldbrook, above the great fall in Dugald Brook, Indian River, eastern Cape Breton, Nova Scotia.

LINGULELLA (LINGULEPIS?) PYGMÆA (Salter).

Plate XXX, figure 10.

Lingula pygmæa SALTER, 1865, Quart. Jour. Geol. Soc. London, vol. 21, p. 102, figs. 8a and 8b, p. 101. (Described as a new species; see p. 557 for copy. Figs. 8a-b are copied in this monograph, Pl. XXX, fig. 10.)

- Lingula pygmæa* Salter, DAVIDSON, 1866, British Fossil Brachiopoda, vol. 3, pt. 7, No. 1, p. 53, Pl. II, figs. 8 and 8a. (Text and figures copied from the preceding reference.)
- Lingula pygmæa* Salter, PHILLIPS, 1871, Geology of Oxford and the Valley of the Thames, p. 68, Diagram XVII, fig. 13. (No text reference.)
- Lingula pygmæa* Salter, MATLEY, 1902, Quart. Jour. Geol. Soc. London, vol. 58, p. 141. (Synonymy given and species mentioned.)

The original description by Salter follows:

Minute, subcylindrical, gibbous; beak somewhat obtuse; anterior margin truncate; shell thin; surface finely striated transversely. Length, $\frac{1}{15}$ inch; width, $\frac{1}{20}$ inch. In the Black shales.

The Black shales are referred to the Upper Cambrian, the locality being in the eastern portion of the Malvern Hills of England. Davidson [1866, p. 53] states that he could only reproduce Salter's description and figure, as he had not seen specimens of the shell. The figure given by Salter [1865, figs. 8a and 8b, p. 101] is that of an elongate, cuneate shell more like the typical form of *Lingulepis* than *Lingulella*. From its form and the fact that it occurs in association with the *Olenus* fauna it is probable that it should be referred to *Lingulepis*.

FORMATION AND LOCALITY.—Upper Cambrian: (304f [Salter, 1865, p. 102]) "Black shales" in the Malvern Hills, between Herefordshire and Worcestershire, England.

LINGULELLA (LINGULEPIS) ROBERTI (Matthew).

Plate XXXVII, figures 4, 4a-d.

- Lingulella roberti* MATTHEW, 1895, Trans. Roy. Soc. Canada for 1895, 2d ser., vol. 1, sec. 4, No. 13, pp. 256-257, Pl. I, figs. 2a and 2b. (Described and discussed as a new species. Plate XXXVII, figs. 4, 4a-d of this monograph are drawn from specimens in Matthew's type material, and it is possible that the specimens represented by figs. 4a and 4b are the ones figured by Matthew, figs. 2a and 2b, respectively, but positive identification is impossible.)
- Lingulepis roberti* MATTHEW, 1903, Geol. Survey Canada, Rept. Cambrian Rocks Cape Breton, p. 132, Pl. VIII, figs. 5a-b. (Text and figures copied from the preceding reference.)

General form elongate ovate, with the ventral valve acuminate and the dorsal round ovate. The cardinal slopes of the ventral valve are in some shells slightly incurved as in *Lingulella (Lingulepis) acuminata* (Conrad); a portion of this curvature, as shown in Plate XXXVII, figures 4 and 4a, may be owing to the lateral compression of the shells. The convexity of the ventral valve is moderate, while that of the dorsal is unusually large (Pl. XXXVII, fig. 4b). This may be owing to the deformation of the shell by lateral pressure in the matrix.

Surface of the shell marked by very fine, obscure, radiating striæ and narrow undulations, and very fine, irregular, concentric striæ between relatively strong striæ and lines of growth. The irregular striæ inosculate, Plate XXXVII, figure 4c, so as to give an appearance much like that of *Obolus (Westonia) ella* (Hall and Whitfield) (Pl. XLVII, fig. 1o). When the thin outer layer is exfoliated, the dark shiny surface of the inner layers shows radiating striæ and concentric lines of growth. The inner surface appears to have been punctate to a moderate degree. The shell is moderately thick and is built up of a thin outer layer and several inner layers or lamellæ that anteriorly are slightly oblique to the outer layer, much as in *Lingulella acutangula* (Roemer).

The largest ventral valve among the type specimens has a length of 13 mm.; width, 9 mm.; the width is narrowed 2 or 3 mm. by the lateral compression. A dorsal valve that is very little, if any, distorted is 10 mm. long and 10 mm. wide. A trace of the pedicle groove in the ventral valve is shown by Plate XXXVII, figure 4a. The area of the dorsal valve is not preserved in any of the specimens sent to me by Matthew.

The cast of the visceral cavity is shown in Plate XXXVII, the ventral valve in figure 4a and the dorsal valve in figure 4b.

The anterior lateral and central muscle scars are seen in the specimens of the type sent me by Matthew. In g and h, figure 4b, of Matthew's figures, the umbonal scar is short and broad, as in *Obolus selwyni* (Matthew) (Pl. XXXVII, fig. 1f).

The markings of the vascular system observed are the main vascular sinuses of the ventral valve, a trace of them in the dorsal valve, and a little of the parietal scar about the visceral cavity in the dorsal valve (fig. 4b).

Observations.—This species is related by its form to *Lingulella (Lingulepis) gregua* (Matthew) and *L. (L.) longinervis* (Matthew), but it differs in its surface characters. In its very fine, irregular striæ and general form it is closely allied to *L. (L.) exigua* (Matthew). The thick, robust shell and numerous strong pits on the inner surface of the shell give the latter a character not seen in *L. (L.) roberti*.

The visceral area and muscular scars of the ventral and dorsal valves are much like those of *Obolus selwyni* (Matthew) (Pl. XXXVII), and in specimens of the same size occupy relatively the same position. The specific variations between the two species appear to be in the shape of the valves and the character of the finer ornamentation of the surface.

Matthew originally [1895, p. 257] referred this species to the Ordovician fauna, but in his review of the Cambrian fauna of Cape Breton [1903, p. 132] it is referred to his lower Etcheminian.

The specific name was given in honor of Mr. J. Alfred Robert, of the Geological Survey of Canada, who collected the specimens of the species.

FORMATION AND LOCALITY.—**Middle Cambrian:** (307d [Matthew, 1903, p. 132]) Sandy limestone of Division E2a? of Matthew's Etcheminian, on Young (McFees) Point [Matthew, 1903, p. 19], near George River station, Cape Breton, Nova Scotia.

LINGULELLA (LINGULEPIS) ROWEI (Walcott).

Plate XXI, figures 4, 4a-b.

Obolus (Lingulepis) rowei WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 334. (Characterized as a new species.)

This shell differs from *Lingulella (Lingulepis) acuminata* (Conrad) and other species of *Lingulella* and *Lingulella (Lingulepis)* in the sharp, fine, concentric ridges of the outer surface, about six to the millimeter. This surface resembles closely that of *Obolus (Palæobolus) brentonensis* Matthew. The material is not well preserved, but there is sufficient to illustrate the form of the valves and the character of the surface. A fragment shows a more attenuate posterior portion of a ventral valve than the one illustrated.

The specific name is given in memory of Mr. R. B. Rowe, assistant geologist of the United States Geological Survey, who collected the material a short time before his death.

FORMATION AND LOCALITY.—**Lower Cambrian:** (14p) Reddish-brown quartzitic sandstone, near Resting (Fresh-water) Springs, which is in the southwest corner of T. 21 N., R. 8 E., on Amargosa River, in the southeastern part of Inyo County, California.

LINGULELLA (LINGULEPIS) SPATULA (Walcott).

Plate XIX, figures 5, 5a-b.

Obolus (Lingulella) spatulus WALCOTT, 1902, Proc. U. S. Nat. Mus., vol. 25, p. 607. (Described and discussed as below as a new species.)

General form of the ventral valve spatulate, the sides sloping from the apex forward with a very slight curvature to the anterior fifth of the shell, where they pass into the broadly rounded frontal margin.

Dorsal valve ovate with the greatest width toward the front. Convexity moderate, and about equal in both valves. A ventral valve 9 mm. in length has a convexity of about 1 mm. A fragment of the outer surface indicates that the surface was relatively smooth, being broken only by fine, scattered striæ of growth. The inner layers show concentric lines, also fine, radiating striæ. The interior of the shell was marked by scattered pustules, concentric striæ, and a few radiating lines.

The largest ventral valve has a length of 9 mm. and a width of 6 mm. A dorsal valve 5 mm. in width has a length of 7 mm.

The only trace of the vascular system preserved is the median ridge of the dorsal valve, which extends forward to the anterior fourth of the shell.

Observations.—This very pretty little shell occurs in abundance in the chocolate brown sandstone interbedded in the shales, just above the massive "Tonto" sandstone. It is distinct

from all other species known to me from the Cambrian rocks of the Grand Canyon region. *Obolus* (*Westonia*) *chuarensis* (Walcott) occurs in a layer of sandstone 50 or 60 feet higher up in the section.

FORMATION AND LOCALITY.—**Middle Cambrian:** (74d) Sandstone beds in "Tonto" shale just above massive sandstones near mouth of Bass Canyon, on the south side of the Grand Canyon of the Colorado, southeast of Powells Plateau, Arizona.

LINGULELLA (LINGULEPIS?) SQUAMOSA (Holl).

Plate XXX, figure 9.

Lingula squamosa HOLL, 1865, Quart. Jour. Geol. Soc. London, vol. 31, pt. 1, p. 102. (Described as a new species; see below for copy.)

? *Lingula squamosa* Holl, DAVIDSON, 1866, British Fossil Brachiopoda, vol. 3, pt. 7, No. 1, p. 41, Pl. II, fig. 7. (Copies the original description and discusses species. Fig. 7 is copied in this monograph, Pl. XXX, fig. 9.)

The original description by Holl follows:

Triangular, broad anteriorly, compressed; beak acute; anterior margin truncate; shell thick, strongly grooved from side to side by imbricating lines of growth. Length, one-fourth inch. In the light-brown felspathic sandstone of the Hollybush series.

The sandstone of the Hollybush series is beneath the Black shales in which *Lingulella* (*Lingulepis*?) *pygmæa* (Salter) occurs, but appears to form a portion of the Upper Cambrian of the Malvern Hills section. The species has a peculiar cuneate form, more like that of *L. (L.) acuminata* (Conrad) than any other European shell known to me. On this account it is referred to the subgenus *Lingulepis*.

FORMATION AND LOCALITY.—**Upper Cambrian:** (304g [Holl, 1865, p. 102]) Sandstones of the Hollybush series, Malvern Hills, between Herefordshire and Worcestershire, England.

LINGULELLA (LINGULEPIS) STARRI (Matthew).

Plate XXXVII, figures 2, 2a-b.

Lingulella starr MATTHEW, 1891, Trans. Roy. Soc. Canada for 1890, 1st ser. vol. 8, sec. 4, No. 6, pp. 146-147, Pl. XV, figs. 5a-c, 6a-b. (Described and discussed as a new species. According to Matthew the type specimens have been mislaid or lost, and the specimens represented in this monograph are from new material collected by him.)

Lingulepis starr MATTHEW, 1903, Geol. Survey Canada, Rept. Cambrian Rocks Cape Breton, p. 195. (Mentioned.)

General form cuneate, elongate ovate, with the ventral valve obtusely acuminate and the dorsal valve broadly ovate; valves appear to have been moderately convex. Outer surface of the shell marked by fine, concentric, slightly irregular striæ, 8 to 12 in the space of a millimeter; when the outer layer of shell is exfoliated coarser concentric striæ are seen; and on the inner surface of the shell strong concentric striæ and numerous radiating striæ occur, the latter being most prominent on the anterior half of the valves. The shell is strong and is built up of a thin outer layer and several inner layers or lamellæ, very much as in *Lingulella acutangula* (Roemer).

A large ventral valve, as measured by Matthew, has a length of 16 mm.; width, 14 mm.

A cast of the interior of a broken ventral valve shows the visceral cavity (v) and a trace of the main vascular sinus (Pl. XXXVII, fig. 2b).

Observations.—This is one of the large species of the genus and compares in this respect with *Lingulella ampla* (Owen) and *Obolus* (*Westonia*) *aurora* (Hall). Matthew wrote me that the type of this species had been mislaid or lost. The illustrations are taken from other specimens identified and labeled by him.

The specific name was given in honor of Mr. R. P. Starr, who discovered the species.

FORMATION AND LOCALITY.—**Upper Cambrian:** (308c [Matthew, 1891, p. 147]) Shales of Division 2b of Matthew's *Johannian* at St. John; and (2x) thin-bedded sandstones of Division 2 of Matthew [1892, p. 59], on the south shore of Long Island, Kennebecasis Bay [Matthew, 1898a, pp. 124 and 127]; both in St. John County, New Brunswick.

LINGULELLA (LINGULEPIS ?) sp. undt. (Walcott).

Obolus (Lingulepis) sp. undt. WALCOTT, 1906, Proc. U. S. Nat. Mus., vol. 30, pp. 567-568. (Characterized as below as an undetermined species.)

This species is represented by a few fragments, one of which shows that the ventral valve is elongate, and the apex acuminate. The shell was built up of several layers or lamellæ, as in characteristic forms of *Lingulella (Lingulepis)*. The interior surface of some of the lamellæ is marked by fine, radiating, and concentric striæ; the outer surface, under a strong magnifier, shows fine, concentric, somewhat irregular striæ.

FORMATION AND LOCALITY.—Middle Cambrian: (C72) Thin green-gray limestone interbedded with ocherous and green clay shales, overlying the massive oolite in the Kichou formation [Willis and Blackwelder, 1907, pp. 139 and 145 (3d list of fossils)], 4 miles (6.4 km.) east of Fanglanchon, Shansi, China.

Genus DELGADELLA Walcott.^a

Delgadella WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 4, Pl. XI, and pp. 142 and 144. (Classification of genus.)

The description of the type species includes all that is known of this genus. The form of the shell is more like that of Lower Ordovician species referred to *Lingula* than to the typical forms of *Lingulella* or *Lingulepis*.

Type.—*Lingulepis lusitanica* Delgado.

The generic name is given in memory of the late Mr. J. F. Nery Delgado, of the Geological Survey of Portugal.

DELGADELLA LUSITANICA (Delgado).

Plate XXIX, figures 5, 5a-b.

Lingulepis lusitanica DELGADO, 1904, Comunicações Comissão Serviço Geológico Portugal, tome 5, fasc. 2, pp. 365-366, Pl. IV, figs. 31-34. (Characterized and discussed in French as a new species. Photographs of the specimens represented by figs. 31, 32, and 34 are reproduced in this monograph, Pl. XXIX, figs. 5a, 5b, and 5, respectively, each individual figure being a reversed view of Delgado's original figure.)

General form elongate ovate, moderately convex. The greatest width of the ventral valve is at the anterior third, whence the outline narrows slightly to the broadly rounded front, and gradually to the subacuminate posterior half.

Dorsal valve unknown, unless Plate IV, figure 17, and possibly figure 27, of Delgado, represents it. However, these two shells are referred in this monograph to *Lingulella delgadoi* (p. 491) as they appear to be more closely related to that species than to *Delgadella lusitanica*.

Shell thick and with a thick margin. This is shown by the casts of the edges of the valves, as shown by figures 5 and 5a. Shell substance unknown. Delgado [1904, p. 365] states that the shells range from 5 to 8.5 mm. in length.

Observations.—Delgado referred this species to *Lingulepis* on account of its general form, but from the fact that it has a thick, strong shell and does not have the attenuated extension of the apex of the ventral valve of the typical forms of *Lingulepis* I am inclined to refer it to a new genus characterized by a thick shell, spatulate form, with a subacuminate beak. A shell agreeing with this in outline and form occurs in the Lower Ordovician shales at Kelleys Island, Conception Bay, Newfoundland.

Delgado [1904, p. 365] compares this species with the very young shells of *Lingula lesueurii* Rouault [Davidson, 1866, Pl. I, figs. 1-11]. If the specimens representing it had been sent to me without any information as to the associated fauna, I should have been strongly inclined to refer them to a Lower Ordovician fauna.

Lingulella (Lingulepis) acuminata meeki (Walcott) has a somewhat similar outline, but that is a thin, corneous shell of the Upper Cambrian fauna. We must await further discoveries of more perfectly preserved material before a more complete description can be given.

^a Prior to the definition of the genus *Delgadella* the type species was described under *Lingulepis* [Delgado, 1904, p. 365].

Mr. Delgado very kindly sent me a specimen of this species, also some large photographs of specimens illustrated by him. I have reproduced three of these in illustration of the species.

FORMATION AND LOCALITY.—**Lower Cambrian:** (351 [Delgado, 1904, p. 365]) Shales at Monte de Valbom, north-east of Villa Boim, Province of Alemtejo, Portugal.

Subfamily ELKANIINÆ Walcott and Schuchert.

Genus ELKANIA Ford.^a

Billingsia FORD [not DE KONINCK, 1876], 1886, Am. Jour. Sci., 3d ser., vol. 31, pp. 466-467. (Described and discussed as a new genus.)

Not *Billingsia* WALCOTT, 1886, Bull. U. S. Geol. Survey No. 30, pp. 5, 21, 60, and 62. (Used in lists for a genus of the Gastropoda.)

Elkania FORD, 1886, Am. Jour. Sci., 3d ser., vol. 32, p. 325. (Proposes *Elkania* for *Billingsia*, which was preoccupied.)

Elkania FORD, HALL and CLARKE, 1892, Eleventh Ann. Rept. State Geologist New York for 1891, p. 241. (Described.)

Elkania FORD, HALL and CLARKE, 1892, Nat. Hist. New York, Paleontology, vol. 8, pt. 1, pp. 75-78. (Copies part of Billings's, 1861b, p. 70, description of "*Obolella desiderata*" and Ford's, 1886a, p. 467, description of the genus, and describes and discusses genus.)

Elkania FORD, WALCOTT (in part), 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 321-323. (Described and discussed essentially as below. The text includes reference to species now placed under *Obolus* (*Fordinia*.)

Elkania FORD, WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 4, Pl. XI, and pp. 142 and 144. (Classification of genus.)

General form ovate, biconvex; shell substance corneous and made up of several thin layers or lamellæ that increase in number toward the front and lateral margins. Surface marked by fine concentric striæ of growth. Apex of both ventral and dorsal valves marginal. The interior of the ventral valve has a thickened posterior section which has a central pedicle furrow and two flexure lines running obliquely forward and outward from the apex, a little inside of the grooves of the main vascular trunks; this structure is apparently the result of the union of the area with the bottom of the shell so as to bring, as the shell grew, the path of advance of the pedicle groove, main vascular sinuses, and lateral muscle scars all on one surface instead of on the area and the shell beneath it as in *Obolus*.

The muscle scars are arranged as in *Obolus*. The transmedian and anterior laterals occur well out toward the margin (Pl. LI, fig. 1) and the space inclosing the central, middle lateral, and outside lateral scars is in the central area, on the front of the slope of the thickened posterior portion of the valve (Pl. LI, figs. 1 and 3a); the points of attachment of the individual muscles can not be distinguished. In the dorsal valve the central and anterior lateral scars are clearly shown in several specimens; the transmedian and outside laterals are situated just outside the main vascular sinus (Pl. LI, fig. 1c). Our knowledge of the vascular markings is limited to the main vascular sinuses, except in one ventral valve, where the inner branches have been preserved; in both valves the main trunk rises near the apex and its path is outlined across the internal cardinal area.

The preceding description differs materially from that of Ford [1886a, p. 467] and Hall and Clarke [1892c, p. 77]. I find the muscle scars as described above and am compelled to consider them as indicating the same muscles as in *Obolus*. That the genus is an advance on *Obolus* in the evolution of the inarticulate brachiopods I quite agree with Hall and Clarke [1892c, p. 165], but not that it is a stage in the transition from *Obolus* to *Trimerella* and its allies. (See remarks on platform, p. 309.) *Elkania* is an *Obolus* with the cardinal areas within the plane of the margins of the valves. In the type species, *Elkania desiderata* (Billings), the area of the ventral valve is entirely within the valve, while that of the dorsal valve has been nearly obliterated in the process of change from an open backward-facing area to an inclosed forward-facing

^a The synonymy for this genus does not give a complete record of the various genera under which the species now included in *Elkania* were formerly placed; it gives only those references in which the genus is discussed or described. To complete the record the following mere generic references are listed:

Obolella Billings [1862d, pp. 69 and 71].

Obolella Davidson [1868, p. 309].

Obolella ? Walcott [1884h, p. 67; 1886b, p. 111].

area. A comparison of the interiors of *Obolus apollinis* Eichwald (Pl. VII, figs. 1-17) with those of *Obolus (Fordinia) bellulus* (Walcott) (Pl. LI, figs. 3a-f) and *Elkania desiderata* (Billings) (Pl. LI, figs. 1, 1a-d) illustrates how little change is necessary to convert the exterior cardinal areas of *Obolus* into the inclosed internal areas of *Elkania*.

As the beaks of *Elkania* are marginal, the pedicle passed out through an opening made by the gaping of the valves.

The three known species of the genus are the type species *Elkania desiderata* (Billings), *E. ambigua* (Walcott), in which the shell is very thick, and *E. ida* (Billings).

Authors have referred frequently to the resemblance between species of *Obolella* and *Elkania desiderata*. This does not appear to exist except in a superficial manner. *Obolella* is a stage in the evolution toward the Siphonotretidae, whereas *Elkania* has no known descendants.

The generic name was given in honor of Dr. Elkanah Billings, of the Geological Survey of Canada.

ELKANIA AMBIGUA (Walcott).

Plate LI, figures 2, 2a-c.

Obolella? ambigua WALCOTT, 1884, Mon. U. S. Geol. Survey, vol. 8, pp. 67-68, Pl. I, figs. 2a-c. (Described and discussed as a new species. The specimens represented by figs. 2a-c are redrawn in this monograph, Pl. LI, figs. 2a, 2, and 2b, respectively.)

Billingsia? ambigua (Walcott), FORD, 1886, Am. Jour. Sci., 3d ser., vol. 31, p. 467. (Generic relations mentioned.)

Elkania ambigua (Walcott), FORD, 1886, idem, vol. 32, p. 325. (Merely changes generic reference.)

Elkania ambigua (Walcott), HALL and CLARKE, 1892, Nat. Hist. New York, Paleontology, vol. 8, pt. 1, p. 78. (Generic relations discussed.)

General form ovate; biconvex; beaks marginal. Surface marked by fine concentric striæ of growth. Substance of shell corneous as far as can be determined, although some of the layers appear to be calcareous. The shell is made up of many thin layers or lamellæ.

Ventral valve elongate oval, moderately convex. Dorsal valve transversely broad ovate; the interior shows a slender median septum at the bottom of a shallow, concave, well-defined visceral area; within the latter area the central muscle scars occur at the outer margins about one-half the distance from the posterior margin to the anterior margin of the visceral area; the anterior lateral scars are close together on each side of the median septum at the anterior margin of the area; the thickening of the shell varies greatly in different shells; in some it extends far to the front (Pl. LI, fig. 2c) and in others it is scarcely noticeable (fig. 2b).

No interiors of the ventral valve have been found and the cardinal area of the dorsal valve is unknown. The largest dorsal valve has a length of 9 mm.; width, 10 mm.

This species in size and form is related to *E. desiderata* (Billings); it differs in the character of the interior of the dorsal valve, and in having a thicker and stronger shell in the adult stage.

When the species was first described its relations were uncertain, hence the specific name.

FORMATION AND LOCALITY.—Lower Ordovician: (63) *Base of the Pogonip limestone, northeast of Adams Hill*; and (202) *Pogonip limestone, on the summit of the ridge directly southeast of the Jackson mine, northwest of Shadow Canyon*; both in the Eureka district [Hague, 1892, Atlas], Eureka County, Nevada.

ELKANIA DESIDERATA (Billings).

Elkania desiderata (Billings), FORD, 1886, idem, vol. 32, p. 325. (Merely changes generic reference.)

Elkania desiderata (Billings), HALL and CLARKE, 1892, Eleventh Ann. Rept. State Geologist New York for 1891, Pl. III, figs. 13 and 14. (No text reference. Figs. 13 and 14 are drawn from casts of the two specimens figured by Billings, 1862d, figs. 62a and 62b, p. 68, the specimens themselves being redrawn in Hall and Clarke, 1892c, Pl. III, figs. 16 and 17, respectively.)

Elkania desiderata (Billings), HALL and CLARKE, 1892, Nat. Hist. New York, Paleontology, vol. 8, pt. 1, pp. 76 and 77, Pl. III, figs. 15-19. (Part of original description, Billings, 1862d, p. 70, copied on p. 76 and species described and discussed. Figs. 16 and 17 are drawn from the specimens figured by Billings, 1862d, figs. 62a and 62b, p. 68; figs. 15 and 18, which represent casts of the specimens represented by figs. 16 and 17, respectively, are copied from figs. 13 and 14 of the preceding reference.)

The species has been so thoroughly described by Billings [1862d, p. 69], Ford [1886a, p. 466], and Hall and Clarke [1892c, p. 77], from their respective points of view, that I will confine my observations to the interior characters. As noted under the genus, I regard the cardinal areas as being reversed; that is, sloping within the plane of the margins of the valves instead of without, as in *Obolus*; the space beneath the area and the bottom of the valve is filled with shell, and the margin of the area thus disappears in the anterior slope of the thickened portion of the shell.

The scheme of muscle scars, as far as they are known, is the same as in *Obolus*. In the ventral valve the anterior laterals (j) and transmedians (i) occur outside the main vascular sinuses toward the margin of the valve and in front of the included cardinal area. The space occupied by the central and middle and outside lateral scars is defined on the front slope of the umbonal thickening of the valve. The muscle scars of the dorsal valve include the transmedian and outside laterals on the outer margin of the main vascular sinuses, and the central and anterior laterals on the margins of the central visceral area.

The vascular markings include the main vascular sinuses in the two valves, and some inner branches in the ventral valve.

Elkania desiderata differs from *E. ambigua* (Walcott), the only related species, in the interior of the dorsal valves, which are the only parts we have for comparison. The shell is also thinner.

FORMATION AND LOCALITY.—Lower Ordovician: (319a) Levis shales, Point Levis, Province of Quebec, Canada.

ELKANIA IDA (Billings).

Plate XXX, figures 20, 20a; Plate LI, figures 4, 4a-c.

Obolella ida BILLINGS, 1862, Geol. Survey Canada, Paleozoic Fossils, vol. 1, p. 71, fig. 63a-b. (Described and discussed as a new species, see below for copy.)

Obolella? ida BILLINGS, WALCOTT, 1886, Bull. U. S. Geol. Survey No. 30, p. 111. (Generic relations mentioned.)

Billingsia? ida (Billings), FORD, 1886, Am. Jour. Sci., 3d ser., vol. 31, p. 467. (Generic relations mentioned.)

Elkania ida (Billings), FORD, 1886, idem, vol. 32, p. 325. (Merely changes generic reference.)

The original description by Billings follows:

Shell small, obtusely ovate, greatest width at or a little in front of the middle, abruptly narrowed to the beaks, sides and front margin uniformly rounded, the front slightly less convex than the sides. Both valves equally and rather strongly convex, most elevated at about one-third the length from the apex, thence sloping with a gentle curve to the sides and front margin, abruptly descending on each side of the beak and umbones. Ventral valve slightly more pointed above than the dorsal; umbo narrowly convex; beak apparently depressed to the level of the lateral margin. Dorsal valve obtusely angular or narrowly rounded at the beak, the latter not visibly distinct from the cardinal edge; umbo obtusely convex. Surface with a somewhat shining aspect, with very fine concentric striae; a few radiating striae are visible on two of the specimens. Shell apparently very thin.

Length of a perfect ventral valve, 2 lines; width, 1½ lines. The length and width of the dorsal valve are about equal.

In some material from the McGill University Museum, kindly lent to me by Sir William Dawson and Dr. Frank D. Adams, I found some fine specimens labeled *Obolella ida*, collected by J. Richardson. These specimens show the characters described by Billings [1862d, p. 71] and in addition the following: The shell is corneous and built up of many lamellæ or layers arranged obliquely to the surface so as to form a thick, strong shell. The interior of the ventral valve has a thickened umbonal portion with a pedicle groove much like that in *E. desiderata* (Billings), but much shorter in proportion; owing to the imperfect condition of the remaining portions, no further details can be determined. The interior of the dorsal valve shows a thickened elevated area like that of the dorsal valve of *E. desiderata* (Pl. LI, fig. 1d), but differently shaped. A large transverse depression just in advance of the posterior margin appears

to be all that is left to indicate the cardinal area; the central muscle scars are situated just in advance of this depression and the anterior laterals at the front end of the visceral area; the position of the transmedian and outside lateral scars is indicated by an elongate scar near the posterolateral margin, just in advance of the traces of the cardinal area. Vascular markings unknown.

This species differs from *E. desiderata* in having a thicker and more convex shell and has a differently shaped visceral area in the dorsal valve.

FORMATION AND LOCALITY.—Lower Ordovician: (319)^a Limestone No. 1 of Billings's section; and (319i) limestone of Billings's section; both at Point Levis, Province of Quebec, Canada.

Subfamily NEOBOLINÆ Walcott and Schuchert.

Genus NEOBOLUS Waagen.

[*psis*, young; and *Obolus*.

- Neobolus* WAAGEN, 1885, Mem. Geol. Survey India, Paleontologia Indica, 13th ser., Salt Range Fossils, vol. I, pt. 4, fas. 5, pp. 756-758. (Described and discussed as a new genus.)

- Neobolus* Waagen, HALL and CLARKE, 1892, idem, p. 84. (Described and discussed.)
- Neobolus* Waagen, WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 3, pp. 72-76. (Described and discussed as below, with the exception of the paragraph describing the two text figures.)
- Neobolus* Waagen, WALCOTT, 1908, idem, vol. 53, No. 4, Pl. XI, and pp. 142 and 144. (Classification of genus.)

General outline of shells broad oval to subcircular; nearly equivalve, moderately convex. Shell substance calcareoconeous and probably phosphatic, structure laminated. Surface with concentric striation. Shell strong for its size and built up on its anterior and lateral margins of several thin layers or lamellæ. Apex of ventral valve small and slightly projecting over a low false area that appears to have an open delthyrium. Apex of dorsal valve marginal.

The interior of the ventral valve has a strong, rounded, central ridge extending from the narrow area, about one-third the length of the shell, and a strong ridge on each side that extends from the same point of origin as the central ridge obliquely forward nearly to the frontal margin of the shell;^b between the central ridge and the posterior portions of the lateral ridges there are slightly concave shelves forming, with the central ridge, a triangular platform, with an open space beneath the concave shelves; numerous radiating striæ occur on the concave shelves and the inner surface of the shell.

Of the muscular impressions in the ventral valve, Waagen wrote [1885, p. 762] that "nothing can be observed." Considered from the point of view of the Trimerellidæ, this may appear to be correct, but if we compare the muscle scars of *Obolus* with what appear to me to be points of attachment of muscles in the specimen represented by Plate LXXXI, figure 2e, there is no difficulty in recognizing a few scars. Just beneath the outer extension of the narrow area of the ventral valve there is a minute, clearly defined, elongate, oval space that corresponds to the divided umbonal muscle scar in *Obolus apollinis* Eichwald; near the outer

^a This is the locality from which the species is listed in the collections of the Geological Survey of Canada. Billings [1862b, p. 71] also identifies the species from No. 2 of his section.

^b I do not find any indication of the incurving of these ridges as described and illustrated by Waagen [1885, p. 762, Pl. LXXXV, fig. 6].

margin, on a line with the anterior portion of the central ridge, there is a narrow elongate space which, under a strong reflected light, is seen to be divided diagonally by a slight, narrow, raised line. Compared with *Obolus* this space is the point of attachment of the transmedian and anterior lateral muscle scars. It is probable that the outside and middle lateral muscle scars and the centrals were attached to the platform, but there are no defined muscle scars upon it.

The interior of the dorsal valve has several very unusual characters. There is no true cardinal area, unless the thick margin of the shell be considered as such; from the center of the cardinal margin a strong flat process marked by concentric lines of growth projects forward into the valve and rises a little above the plane of the margin of the valve. Waagen [1885, p. 763] calls attention to the resemblance between this process and the tooth of *Trimerella lindströmi*. From beneath the median process a short, thick platform projects upward and forward into the valve (Pl. LXXXI, figs. 2f, 2g, and 2h); it is as wide as the process at its base, expanding toward its front margin. It is concave between its lateral crests, and the outer slopes are slightly concave from the crest to the body of the shell; in front the concave space and crests terminate rather abruptly above the front face, which in turn is underlain by a transversely hollow space of unknown extension beneath the platform. Toward each end of the frontal area a minute depression appears to indicate the point of attachment of a muscle. A narrow, rounded median septum extends from beneath the platform well toward the front of the shell. Two more or less interrupted and obscure ridges, indicating the main vascular trunks, extend from the front anterolateral angles at the base of and at the side of the platform obliquely outward into the valve. The elongate smooth spaces outlined by Waagen [1885, Pl. LXXXV, fig. 6] in his illustrations of this valve are too indefinite to be given form in the drawing of the only specimen showing the interior. What appears to be a small muscle scar occurs at the cardinal angle; it corresponds in position to the transmedian scar of *Obolus*.

Figure 47A, page 567, shows the area, median ridge, and side ridges of the visceral area of the dorsal valve. The platform shown by Plate LXXXI, figure 2f, has not been developed beyond the first stages of its growth. It is probable that the fully developed platform occurs only in very old shells. There is no trace of a platform in the specimen represented by Plate I, figure 3, but it may have been broken away. In another shell, not illustrated, there is no trace of thickening beneath the visceral area. In a section of the platform, median ridge, and vascular sinuses taken where they unite with the inner surface of the dorsal valve (fig. 47B, p. 567) the platform appears to be intermediate in development between the platforms represented by figure 47A, page 567, and Plate LXXXI, figure 2f.

Type.—*Neobolus warthi* Waagen.

Observations.—Through the courtesy of Dr. T. H. Holland, director of the Geological Survey of India, I received the type specimens of *Neobolus*, *Davidsonella*, and *Lakhmina*, studied, described, and illustrated by Waagen. With these before me I find that the elaborate figures of Waagen [1885, Pl. LXXXV] are diagrammatic to a considerable extent, also that I can not clearly recognize some of the characters noted by Waagen.

Waagen's original description [1885, p. 762] of the genus "*Davidsonella*" is very full and he also gives a detailed description of the type species "*D. linguloides*." Oehlert [1887, p. 1265] evidently based his description of "*Lakhmina*" on Waagen's description and illustrations, apparently not noting that Waagen stated in his text [1885, p. 762] that the elongate area on the sides of the interior of the shell were not muscle scars, but that he considered them as smooth areas outside the crescent.

Oehlert [1887, p. 1265], when describing the genus *Lakhmina*, says, "with a straight and projecting beak perforated for the passage of the foramen." He reproduces Waagen's figures and shows a deep pedicle furrow. This leads me to think that he had Waagen's description and figures in mind when writing his diagnosis of *Lakhmina*. Only one shell shows the apex of the ventral valve and the small false area beneath, and one other of the interior shows the true area and a triangular depressed spot at the center; a fracture at the center has broken

out a bit of the shell which gives rise to the narrow, deep furrow described by Waagen. The ventral valve has (a) a false area beneath the apex, and (b) a true area on a plane with the margins of the valve.

When looking over the types of *Neobolus* and *Lakhmina* for the purpose of having illustrations made of them, I noted that there was a strong resemblance between the shells of the two genera, but having the impression that the ventral valve of *Lakhmina* had a pedicle opening at the apex, drawings were arranged on the plates under the conception that *Lakhmina* belonged with the Neotremata. Schuchert noted the same resemblance when looking over the plates of this monograph and called my attention to it. I then made a careful study of all of the specimens and by the use of acid developed several interiors of dorsal valves. I found that the supposed perforation of the apex of the ventral valve of *Lakhmina* was the result of the breaking out of the minute apex; that the dorsal valve of *Neobolus warthi* was the same as the dorsal valve of *Lakhmina linguloides* and that two genera and four species had been based on specimens of *Neobolus warthi*.

The external characters of all of the shells referred to *Neobolus* and *Lakhmina* are the same. Only one specimen of the interior of the ventral valve that shows anything of the platform beneath the visceral area occurs in the collections; this was referred to *Lakhmina* by Waagen, but the accompanying dorsal valves were first described as *Neobolus*. By comparing the illustrations of Waagen [1891, Pl. II] the student will notice that figure 8c of the interior of the dorsal valve of *Neobolus* is essentially the same as the interior of the dorsal valve of *Lakhmina* (fig. 4c) with the exception of the thickened platform.

It may seem as though it were forcing unlike forms into one species to place the specimen represented by Plate LXXXI, figures 2f, 2g, and 2h, with those represented by figures 47A and 47B, page 567, but with our present information it appears to be necessary to do so.

All authors have classified the shells described as *Lakhmina linguloides* with *Trimerella*, and Hall and Clarke [1892c, p. 29] state that in the present condition of knowledge it must be regarded as the earliest representative of the trimerelloid Brachiopoda. The external form is similar to that of *Obolus* and the interior characters might readily have been developed from that genus, but the platform is posterior and not central as in the trimerelloids.

NEOBOLUS WARTHI Waagen.

The generic description embraces the characters of the species. By the courtesy of Dr. T. H. Holland, director Geological Survey of India, I have had the opportunity of studying the type material and thus of coming to an independent opinion as to the genus and species.

Waagen [1885, p. 758] states that the surface of the shell is perfectly smooth. I find that some of the specimens are worn nearly smooth, while others preserve concentric lines and striæ of growth. The shells show the same variation of surface as do shells of *Obolus* that have lived on a sandy bottom and been more or less worn by the attrition of the sand.

The second species of the genus, "*Neobolus wynnei*," differs from the types of *Neobolus warthi*, according to Waagen [1885, p. 760], only in having the surface striæ more distinctly preserved. This character does not appear to be of specific value, as there is considerable variation in this respect among the type specimens of *Neobolus warthi*.

The relations of *Neobolus warthi* and *Lakhmīna linguloides* have been mentioned under observations on the genus *Neobolus* (page 565).

The shell described as "*Davidsonella squama*" by Waagen [1885, p. 766] appears to be a dorsal valve of "*Lakhmīna linguloides*." He figures it [1891, Pl. II, figs. 6a-b] as *Neobolus warthi*. I found some rock attached to the cardinal margin in such a manner as to give the effect of a low pointed apex. On clearing the rock away the apex was found to be marginal and the cardinal border the same as in the dorsal valves of "*Lakhmīna linguloides*." The shell is the largest found at Jutána. It has a length of 13 mm.; width, 14.5 mm.

The specific name was given in honor of Dr. H. Warth.

FORMATION AND LOCALITY.—Middle Cambrian: Lower portion of the "*Neobolus* beds" of the Khussak group, in purplish-colored, fine-grained, micaceous sandstones at the following localities [Waagen, 1885, p. 759]; (357c) near the fresh-water springs in a gorge above the salt mines at Kiura (Khewra); (357a) at Jutána; and (357b) at Chél Hill; all in the Salt Range, India.

FIGURE 47.—*Neobolus warthi* Waagen. A, Interior of dorsal valve showing area, median ridge, and thickening of the shell beneath the visceral area. On the right side the main vascular sinus is clearly shown. This drawing is from a cast of a dorsal valve in which the platform has not been developed. B, Outline of a platform, median ridge, and vascular sinuses in a dorsal valve, obtained by removing the outer shell by acid ($\times 3$). (See p. 565.)

The specimens represented by figures 47A and 47B were collected in the Khussak group of the Middle Cambrian at Kiura (Khewra), Salt Range, India. The specimen represented by figure 47A is shown in Plate I, fig. 4b, also, the present figure being the correct and later drawing from a cast made in a natural mold. The specimen from which the cast was taken is in the collection of the Geological Survey of India (Cat. No. 3/780).

Subfamily BICIINÆ Walcott and Schuchert.

Genus BICIA Walcott.^a

Bicia WALCOTT, 1901, Proc. U. S. Nat. Mus., vol. 23, pp. 676-678. (Described and discussed as below as a new genus.)
Bicia WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 4, Pl. XI, and pp. 142 and 144. (Classification of genus.)

Shell subequivalve, moderately convex, longitudinally ovate, with the ventral valve sometimes subacuminate and the dorsal valve subcircular. Beak of both valves as now known terminates at the posterior margin. Surface marked by concentric and radiating striae.

Shell substance unknown in an unaltered condition. Shell structure formed of a thin surface layer and numerous inner layers or lamellæ more or less oblique to the outer layer. Area of the ventral valve usually on the plane of the edges of the valve, but in some instances it rises at a low angle; it is usually high and triangular in outline, but the apex may be rounded and the base curved forward at the median line; divided midway by a narrow pedicle furrow and again at each side by a narrow flexure line that extends forward and outward from the apex. Area of dorsal valve short; it appears in both of the known species to rise from the plane of the edges of the valve. Striae of growth subparallel to the base across the areas.

The main vascular sinuses of the ventral valve are narrow and extend forward from the projecting center of the base of the area, gradually separating as they cross the visceral area and extend forward beyond the transverse center of the shell. In the dorsal valve they appear to separate more rapidly and to follow the outer margin of the central cavity, except in the second species. A narrow median septum is indicated in the dorsal valve on the crest of a strong median ridge.

One of the striking features in both of the known species of this genus is the oblong oval boss (b) that is present in the ventral valve of most adult shells; it is situated each side of the forward projecting central portion of the area, with the larger axis extending forward and outward when the shell is subacuminate, and transverse when the shell is broadly rounded; in the dorsal valve of *Bicia gemma* (Billings) it is not so well defined as in *B. whiteavesi* Walcott; the boss (b) is bounded by the margin of the base of the area, the narrow elongate sulcus containing the marginal muscle scars and the base of the main vascular sinuses. In *B. whiteavesi* it reaches its greatest development in both valves, resembling in position and surface characters the posterior occlusor scars of *Pholidops implicata* von Huene [1899b, p. 278, Pl. X]. Somewhat similar bosses occur in the ventral valve of *Obolella crassa* (Hall) and *Obolus apollinis* Eichwald, but they are not developed to the extent they are in *Bicia*. They appear to occur only in those thick shells that have deposits of shell substance over the visceral area.

The outline of the parietal scar in the ventral valve is well shown by Plate L, figure 1g; it incloses a heart-shaped visceral area in the ventral valve closely circumscribing the muscle scars; its general course in the dorsal valve is suggested by the position of the muscle scars.

Five pairs of muscle scars have been observed. The rather large central scars (h) in the dorsal valve are placed close to the broad median ridge, a little back of the center; the small anterior laterals (j) are slightly in advance of the centrals on the median ridge, close to the median line; the transmedian scars (i) are almost under the edge of the area and near the outer margin; the outside (l) and middle (k) laterals are slightly in advance and farther out than the transmedian scars. The centrals, middle laterals, and outside laterals of the ventral valve are grouped in the narrow space on each side of the U-shaped forward-projecting portion of the visceral area (c, fig. 2); traces of individual scars have been seen, but they can not be separated so as to identify them; the transmedian (i) and anterior lateral (j) scars are close to the outer margin of the ventral valve and just in advance of the oblong boss in front and each side of the forward-projecting base of the area; umbonal and pedicle scars unknown, except what may possibly be a small umbonal scar in the dorsal valve of *B. whiteavesi* Walcott [Pl. L, fig. 2e, at g].

^a Prior to the definition of the genus *Bicia* the type species was described under the following genera:

Obolella Billings [1872a, p. 218; 1872b, p. 357].
Obolella Walcott [1886h, p. 116; 1891a, p. 612].

Obolella Hall and Clarke [1892c, pp. 69 and 71].

Type.—*Obolella gemma* Billings. Second species: *Bicia whiteavesi* Walcott.

Observations.—*Bicia* is a form that combines many of the characteristics of *Obolella* and *Obolus*. It resembles *Obolella* in the arrangement of the muscle scars and main vascular sinuses of the interior of the valves. It differs in having a high area with an open pedicle groove in the ventral valve and an elevated ridge or boss in the back portion of the dorsal valve that in one species, *B. whiteavesi*, is very prominent. The ensemble of the dorsal valve of *Bicia* is unlike that of either *Obolella* or *Obolus*. *Bicia* with its thick shell, high area, deep central cavity (heart-shaped cavity of Mickwitz [1896, p. 71]), arrangement of visceral cavity, muscle scars, and vascular markings in the ventral valve, is a true *Obolus* of the *O. apollinis* Eichwald type; but in its more elongate outline, strongly striated surface, and in nearly all details of the dorsal valve it is quite distinct.

Of the two species now referred to the genus, *B. gemma* (Billings) has an unusually thick shell and a very marked deposit of shell substance over the visceral area in the ventral valve, the posterior portion of the same area in the dorsal valve, and along its median line. In the second species there is a considerable deposit over the same area, with the exception of the median line, where the strong median ridge is absent.

The generic name is derived from the town of Bic, Quebec, near which the type species was found.

BICIA GEMMA (Billings).

Plate L, figures 1, 1a-n.

Obolella gemma BILLINGS, 1872, Canadian Naturalist, 2d ser., vol. 6, No. 2, pp. 218-219; fig. 5, p. 217. (Described and discussed as a new species.)

Obolella gemma BILLINGS, 1872, Am. Jour. Sci., 3d ser., vol. 3, p. 357, fig. 5, p. 355. (Described and discussed. Fig. 5 is copied from fig. 5 of the preceding reference.)

Obolella gemma BILLINGS, WALCOTT, 1886, Bull. U. S. Geol. Survey No. 30, pp. 116-117, Pl. X, figs. 2, 2a-e. (Copies the original description, Billings, 1872a, pp. 218-219, and discusses species. The specimens represented by Pl. X, figs. 2b, 2c, 2d, and 2e, are redrawn in this monograph, Pl. L, figs. 1i, 1j, 1k, and 1c, respectively.)

Obolella gemma BILLINGS, WALCOTT, 1891, Tenth Ann. Rept. U. S. Geol. Survey, p. 612, Pl. LXXI, figs. 5, 5a-c, Pl. LXXII, figs. 2 and 2a. (No text reference. Figs. 5, 5a-c are copied from Walcott, 1886b, Pl. X, figs. 2, 2d, 2b, and 2c, respectively; Pl. LXXII, figs. 2 and 2a, are copied from Walcott, 1886b, Pl. X, figs. 2a and 2e, respectively.)

Obolella gemma BILLINGS, HALL and CLARKE, 1892, Nat. Hist. New York, Paleontology, vol. 8, pt. 1, pp. 69 and 71; fig. 30, p. 71; and Pl. II, figs. 42-44. (Discussed under the genus *Obolella*. Fig. 30, p. 71, is copied from Walcott, 1886b, Pl. X, fig. 2d; Pl. II, fig. 42, is drawn from the specimen figured by Walcott, 1886b, Pl. X, fig. 2a.)

Bicia gemma (Billings), WALCOTT, 1901, Proc. U. S. Nat. Mus., vol. 23, pp. 678-680. (Described and discussed as below.)

General form ovate, with ventral valve subacuminate when the beak is extended, or obtusely acuminate when the beak is rounded; dorsal valve oval to subcircular in outline; the range of variation in the outline of the valves is shown by the figures on Plate L. The convexity of the valves is fairly strong and nearly the same in each where they are embedded in the same matrix.

Surface of shell marked by numerous slightly irregular concentric striæ and lines of growth, by fine radiating striæ between stronger radiating lines, and on some shells by strongly developed, elevated, radiating striæ; the radiating striæ are often slightly irregular and interrupted, as shown by figure 1a. When the outer surface is partly worn away it is smooth, or the shell has a peculiar surface formed by traces of the radiating, interrupted, or undulating striæ (fig. 1d). The concentric striæ and lines of growth are shown on the outer surface of the inner layers of the shell and on the interior surface where rather strong radiating striæ are often beautifully shown.

The shell is unusually thick and strong for one so small; those from St. Simon and Troy appear to be calcareous and formed of one solid layer; this is probably owing to their condition of preservation, as in a weathered specimen lamellæ oblique to the outer surface are clearly shown, and indications of lamellæ on the central and posterior portions point to the same shell structure as in *Obolus* and *Obolella*.

The ventral valves average about 5 mm. in length, the largest being 7 mm.; average width 4 mm., largest 5 mm. The dorsal valve is about one-fifth shorter than the ventral.

The area of the ventral valve is usually on the plane of the margins of the valve, but in many specimens it rises at angles varying from 1° to 10°; it is high and narrow, somewhat as in *Obolus (Schmidtia) acuminatus* Mickwitz (Pl. XIV, figs. 2, 2a) and divided midway by a strong, rounded, narrow pedicle furrow; the striae of growth are rather coarse and arch forward at the center and across the pedicle furrow, following the contour of the base of the area; the position of the flexure line is sometimes clearly shown by a narrow depression. The area of the dorsal valve is short and easily escapes observation except in well-preserved shells; it sometimes has a slight central pedicle depression and often is only a short, almost smooth surface extending well out on the cardinal slopes of the valve.

The muscle scars as far as determined are arranged as in *Obolus*. The umbonal and pedicle scars have not been observed. The elongate, oval central scars (h) are rather large in the dorsal valve and situated on each side of the strong median ridge about the middle of the valve; in the ventral valve they are crowded in with the scars of the middle and outside laterals; the anterior laterals (j) are barely discernible in one specimen of the dorsal valve as small oval dots on the central ridge a short distance in advance of the centrals; in the ventral valve they are close to the base of the area and near the outer edge of the shell; the middle and outside laterals in the ventral valve are situated in the trapezoidal area (c), but do not appear to be separable on the specimens in the collection; in the dorsal valve they are well shown in advance of the transmedian scar (i). The latter (i) in the ventral valve is merged with the anterior laterals (j).

Of the vascular markings the main sinuses of the ventral valve are about all that is clearly shown, although the position of the parietal scar is indicated in advance of the center of the shell (fig. 1g). One of the most strongly marked characters of the dorsal valve is the median ridge (mr); it varies in strength and outline in different shells, but is usually a prominent feature; it extends to the frontal margin in most shells, but in some it narrows and is less prominent anteriorly. A few specimens show a slight depression crossing it just in front of the central scars, and one has two minute anterior lateral muscle scars directly on the ridge, the parietal scar passing across just in front of them. The thickened shell beneath the visceral cavity of the ventral valve is present in nearly all adult shells; it varies greatly in size, form, and thickness; in some valves it covers the entire area within the parietal scar (Pl. L, figs. 1h and 1k), and in others only a portion (Pl. L, fig. 1i). The thickening in the dorsal valve is along the posterior border of the central cavity; this is best shown in the cast (Pl. L, fig. 1l). The median ridge is also frequently more or less enlarged.

FORMATION AND LOCALITY.—Lower Cambrian: (2o) Limestone boulders in conglomerate on shore at east entrance to harbor at Bic, Rimouski County; (2p) limestone on south side of the road a little west of Bic, and half mile (0.8 km.) west of the road leading to the wharf, Rimouski County; and (319b) limestone boulders in conglomerate at St. Simon, Rimouski (?) County; all in the Province of Quebec, Canada.

(392c [Billings, 1872a, p. 218] *At the Straits of Belleisle, Labrador.*

(32a) Limestone 0.75 mile (1.2 km.) west of Riders Mills on the Harlem Extension Railroad, about 9 miles (14.4 km.) north-northeast of Chatham, Kinderhook quadrangle (U. S. Geol. Survey), Columbia County; (27) even-bedded and conglomeratic limestones on the ridge in the eastern suburb of Troy, Rensselaer County; (29a) limestone 1 mile (1.6 km.) below the New York Central Railroad depot at Schodack, Rensselaer County; and (2b) limestone just north of Beman Park, in the northeastern part of the city of Troy, Troy quadrangle (U. S. Geol. Survey), Rensselaer County; all in New York.

BICIA WHITEAVESI Walcott.

Plate L, figures 2, 2a-e.

Bicia whiteavesi WALCOTT, 1901, Proc. U. S. Nat. Mus., vol. 23, p. 680. (Characterized and discussed as below as a new species.)

This species is associated with *Bicia gemma* (Billings) in a bedded limestone at Troy, New York. It differs from the latter, in the dorsal valve, in the absence of the median ridge; the presence of a broad area; in the presence in the interior of both valves of two large,

circular, scarlike spots, one on each side of the median line and just in front of the area, that recall in appearance and position the posterior adductor scars of *Crania*. The ventral valve is so much like that of *B. gemma* (Billings) that it is difficult to decide whether such shells as are represented by Plate L, figures 2a and 2b, should not be referred to *B. gemma*. There is a gradual transition in form and character of the interior of the ventral valve between the extremes represented in *B. gemma* by figures 1h and 1i, through figures 1f, 1g, 1k, 2a, and 2b, to the extreme form of *B. whiteavesi*, figure 2c. If it had not been for the bosses in figure 2c, and the dorsal valve, figure 2e, associated with it, I would have hesitated to refer it to a distinct species.

The specific name is given in honor of Prof. J. F. Whiteaves, of the Geological Survey of Canada.

FORMATION AND LOCALITY.—Lower Cambrian: (2b) Limestone just north of Beman Park, in the northeastern part of the city of Troy, Troy quadrangle (U. S. Geol. Survey), Rensselaer County, New York.

Genus DICELLOMUS Hall.^a

Dicellomus HALL, 1873, Twenty-third Ann. Rept. New York State Cab. Nat. Hist., p. 246. (Characterized as a new genus.)

Schmidtia ZITTEL (in part) [not VOLBORTH], 1880, Handbuch der Palæontologie, Bd. 1, Abth. 1, p. 665. (Doubtfully places *Dicellomus* as a synonym of *Schmidtia*.)

Obolella BILLINGS, HALL and CLARKE (in part), 1892, Eleventh Ann. Rept. State Geologist New York for 1891, pp. 240-241. (*Dicellomus* is included with *Obolella* as a synonym.)

Obolella BILLINGS, HALL and CLARKE (in part), 1892, Forty-fifth Ann. Rept. New York State Museum for 1891, pp. 556-557. (Copy of preceding reference.)

Obolella BILLINGS, HALL and CLARKE (in part), 1892, Nat. Hist. New York, Paleontology, vol. 8, pt. 1, pp. 66-73, especially pp. 72-73. (*Dicellomus* is discussed as a synonym of *Obolella*.)

Dicellomus HALL, WALCOTT, 1899, Mon. U. S. Geol. Survey, vol. 32, pt. 2, p. 446. (Discussed, part of the paragraph being copied below, see p. 572.)

Dicellomus HALL, WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 312-313. (Described and discussed essentially as below.)

Dicellomus HALL, GRABAU and SHIMER, 1907, North American Index Fossils, vol. 1, p. 189. (Described.)

Dicellomus HALL, WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 4, Pl. XI, and pp. 142 and 144. (Classification of genus.)

Shell small; general form ovate to subsemicircular, biconvex, with apices marginal. Surface of outer shell finely punctate in all species where it is preserved uninjured. Interior or middle lamellæ marked by radiating striæ and minute punctæ; inner surface finely punctate. The shell is thick in all the species now known, and is built up of a thin, outer, scabrous layer, numerous inner layers or lamellæ, and a thin inner layer. Shell substance apparently calcareo-corneous.

The interior of the ventral valve (Pl. LII, figs. 1c, 1d) shows a short area with a median pedicle groove; an elongate visceral area; well-marked main vascular sinuses; large, composite scars (cl) where the posterior muscles, i. e., transmedian and outside and anterior laterals, were attached; and a short shelf that extended into the valve from each side of the pedicle groove. This extension appears to correspond to the dental plate in the articulate brachiopods, and it has a slight thickening at the anterolateral margin that suggests a short tooth. In material received from Prof. W. A. Finkelnburg from Hudson, Wisconsin, I worked out several interiors of the ventral valve and found in all of them more or less of the remains of a lining of the pedicle

^a The synonymy for this genus does not give a complete record of the various genera under which the species now included in *Dicellomus* were formerly placed; it gives only those references in which the genus is discussed or described. To complete the record the following mere generic references are listed:

Obolus Owen [1852, p. 501].

Lingula Hall [1861, p. 24].

Obolella Billings [1861b, p. 7; 1861c, p. 946].

Lingula Hall [1862, p. 435].

Obolella Billings [1862c, p. 421; 1862d, p. 67; 1862e, p. 218].

Obolella Meek and Hayden [1862, p. 435].

Lingulepis Meek and Hayden [1865, p. 3].

Obolella Meek and Hayden [1865, p. 4].

Obolella ? Hall † 867, p. 112].

Obolus Whitfield [1875, p. 103].

Obolus ? Whitfield [1880, p. 338].

Obolella Whitfield [1880, pp. 339 and 340].

Obolella Walcott [1886b, p. 111].

Obolella Schuchert [1897, p. 275].

Dicellomus Walcott [1901, p. 673; 1908d, p. 77].

tube that extended on each side above the plane of the cardinal area so as to form a concave plate similar to the posterior portion of the spondylium in *Syntrophia* (Pl. CII, fig. 6f). If the sides of the plate were extended farther and united about the pedicle, a tube would result similar to that of *Obolella* (Pl. LV, figs. 1f and 1h), and ultimately to that of *Botsfordia* (Pl. LVII, figs. 4c and 4g). This plate in *Dicellomus*, while suggesting a spondylium, is more naturally interpreted as the beginning of a pedicle tube.

The interior of the dorsal valve has a well defined but very narrow area in one species, *D. politus* (Hall), that is hollowed out so as to form a shallow groove on each side, apparently for the reception of the short tooth of the ventral valve. No good posterior margins of the valve could be found of the other species of the genus. The composite-scar is large, and in one shell it is subdivided into three small scars that were the points of attachment of the transmedian and outside and middle laterals. The central and anterior lateral scars are arranged as in *Obolus*; the centrals are large and located on the sides of the visceral area; the anterior laterals are small and are located at the anterior end of the visceral area.

Type.—*Lingula polita* Hall.

Observations.—When referring to *Dicellomus* in 1899 I said [1899, p. 446]:

When proposing that the genus *Dicellomus* include *Obolella polita*, Professor Hall [1873, p. 246] stated that the grooving or emargination of the apices of both valves and the thickening of the edges of the shell on each side below the apex, together with the form and character of the muscular impressions, would separate the species from *Obolella*. Again, Messrs. Hall and Clarke [1892c, p. 72] gave a fuller description of *Dicellomus politus*, but owing to the poor character of the material they did not feel confident that it should be recognized as generically distinct from *Obolella chromatica*. Material now in the collections of the United States Geological Survey clearly shows that Professor Hall's provisional conclusion was correct, and that *Dicellomus politus* is generically distinct from *Obolella chromatica*.

The presence of the large, composite, cardinal muscle scars in each valve suggests that a search be made for a foraminal opening, as in *Obolella*, *Linnarssonella*, and *Acrotreta*. No trace has been found externally, and the interior of the ventral valve does not show evidence of it, except in the pedicle plate. *Dicellomus* appears to include characteristics of *Obolus* and *Obolella*, and the presence of incipient dental plates, teeth, and dental grooves suggests an articulate shell.

DICELLOMUS APPALACHIA Walcott.

Plate LIII, figures 4, 4a-g.

Dicellomus appalachia WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 314. (Described and discussed as below as a new species.)

This shell has been identified with *D. politus* (Hall) in the preliminary studies of the genus *Dicellomus*. I find that while it has the same type of shell structure and general form, it differs in being less elongate proportionally and in the details of the form and positions of the muscle scars and vascular markings of the interior of the valve; it differs in the latter respect from *D. nanus* (Meek and Hayden). The outer thin layer has a dull, finely roughened surface that is minutely punctate. When the outer layer is exfoliated the surface of the layer beneath is highly polished and marked by exceedingly fine radiating and concentric striæ and lines of growth. The interior of the dorsal valve shows the large central muscle scars with the minute anterolateral scars almost in contact with them. A composite scar (cl, Pl. LIII, fig. 4d) shows the separate points of attachment of the transmedian (i), outside lateral (l), and middle lateral (k) scars. The variation in the length of the visceral cavity of the dorsal valve, as shown in Plate LIII, figures 4d to 4g, is very great, and it may be that figures 4f and 4g belong to another species.

This species occurs in great abundance in both limestones and shales. It is the Appalachian representative of the widely distributed *D. politus* of the interior of the continent, hence the specific name.

FORMATION AND LOCALITY.—Middle Cambrian: (2z) Nolichucky (?) shale [Campbell, 1899, p. 3], near Shipley Ferry, 0.75 mile (1.2 km.) northwest of Bethany Chapel, northeastern corner of the Roan Mountain quadrangle (U. S. Geol. Survey); (2z') shales in the Honaker limestone [Campbell, 1899, p. 3], at Wallace switch, about 5 miles (8 km.) northeast of Bristol, Bristol quadrangle (U. S. Geol. Survey); and (374c) sandy shale (Nolichucky?) [Campbell, 1899,

p. 3], 8 miles (12.8 km.) northeast of Shipleys, near the line between the Roan Mountain and Bristol quadrangles (U. S. Geol. Survey); all in Sullivan County, Tennessee.

(103a) Upper part of the second shale south of the ridge of sandstone in the Rome formation ("Town Knobs"), on the road from Rogersville to Dodson Ford, near the line between the Morristown and Greeneville quadrangles (U. S. Geol. Survey); (102) Rogersville shale just south of road, one-half mile (0.8 km.) southwest of Rogersville, on the road to Melinda Ferry [Keith, 1896a, areal geology sheet]; (104) shale in railroad cut 0.5 mile (0.8 km.) from Rogersville on the road to Holston River, near the line between the Morristown and Greeneville quadrangles (U. S. Geol. Survey); (124a) shale (Nolichucky?) overlying the limestone which rests on the Rogersville shale, on Big Creek, southeast of Harlan Knob, 4 miles (6.4 km.) northeast of Rogersville [see Keith, 1905, p. 4, and areal geology sheet]; and (374b) shale 1.25 miles (2 km.) from Rogersville, near the line between the Morristown and Greeneville quadrangles (U. S. Geol. Survey); all in Hawkins County, Tennessee.

(107) Limestone in Bull Run; and (107b) shales in railroad cut in Bull Run; both northwest of Copper Ridge [Keith, 1896b, areal geology sheet], 11 miles (17.6 km.) northwest of Knoxville, Knox County, Tennessee.

(11a) Sandstone between First and Armstrong creeks, in the southeast corner of the Maynardville quadrangle (U. S. Geol. Survey), Union County; (117c) shale at Buckingham Ford on Hollis Creek, 5 miles (8 km.) southeast of Greeneville, Greene County; (374a) limestones 2 miles (3.2 km.) south of Coal Creek, Anderson County; and (119) limestone in various localities in Jefferson and Hawkins counties; all in Tennessee.

(16) Conasauga limestone, Blountsville Valley, Blount County; (89) limestone in *Murphrees Valley, Blount County*; (90a) shales at Cedar Bluff, Cherokee County; (90b) Conasauga limestone, in cut on Louisville and Nashville Railroad, near Woodstock, Bibb County; (144c) limestone near the top of the beds exposed near N. K. Burns's barns, near Swansea (Viola), Blount County; and (91) Conasauga ("Coosa") shale, at Cedar Bluff, Cherokee County; all in Alabama.

(47h) Shales on Wolf Creek, 6 miles (9.6 km.) below Rocky Gap, Bland County, Virginia.

DICELLOMUS NANUS (Meek and Hayden).

Plate LIII, figures 1, 1a-1, 2, 2a, 3, 3a-d.

Obolella nana MEEK and HAYDEN, 1862, Proc. Acad. Nat. Sci. Philadelphia for 1861, vol. 13, pp. 435-436. (Described and discussed as a new species.)

Obolella nana Meek and Hayden, HAYDEN, 1862, Am. Jour. Sci., 2d ser., vol. 33, p. 73, figs. 1a-b and 2a-b. (Characterized and discussed. The two specimens represented by figs. 2a and 2b are redrawn in this monograph, Pl. LIII, figs. 2a and 2, respectively.)

Obolella nana Meek and Hayden, BILLINGS, 1862, Geol. Survey Canada, Paleozoic Fossils, vol. 1, pp. 67-68. (Original reference, Meek and Hayden, 1862, pp. 435-436, copied.)

Obolella nana MEEK and HAYDEN, 1865, Smithsonian Contrib. Knowl., No. 172, Paleontology Upper Missouri, pt. 1, p. 4, Pl. I, figs. 3a-d. (Described and discussed. Figs. 3a-b and 3c-d are copied from Hayden, 1862, p. 73, figs. 2a and 2b, respectively.)

Obolella nana Meek and Hayden, WHITFIELD, 1880, U. S. Geog. and Geol. Survey Rocky Mtn. Region, Rept. Geology and Resources Black Hills of Dakota, by Newton and Jenney, pp. 340-341, Pl. II, figs. 14-17. (Copies the description given by Meek and Hayden, 1865, p. 4, and discusses species. Fig. 17 is copied from Meek and Hayden, 1865, Pl. I, fig. 3d.)

Obolella nana Meek and Hayden, WALCOTT, 1886, Bull. U. S. Geol. Survey No. 30, p. 111. (Discussed.)

Obolella nana Meek and Hayden, HALL and CLARKE, 1892, Nat. Hist. New York, Paleontology, vol. 8, pt. 1, pp. 69-70. (Discussed.)

Dicellomus nanus (Meek and Hayden), WALCOTT (in part), 1899, Mon. U. S. Geol. Survey, vol. 32, pt. 2, p. 447, Pl. LX, figs. 3a-d (not fig. 3). (Synonymy and new localities given. Figs. 3b and 3d are drawn from the specimens figured by Hayden, 1862, p. 73, figs. 2a and 2b, and are redrawn in this monograph, Pl. LIII, figs. 2a and 2, respectively. The specimens represented by figs. 3a and 3c are not figured in this monograph. The specimen represented by fig. 3 is referred in this monograph to *Lingulella desiderata*.)

Dicellomus nanus (Meek and Hayden), WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 314-315. (Described and discussed essentially as below.)

The principal characters of this species are the same as *Dicellomus politus* (Hall). The two forms differ exteriorly in *D. nanus* being more convex on the umbones and less elongate. The interior of the ventral valve shows a less elongate visceral area, a relatively larger composite muscle scar (cl); the interior of the dorsal valve of *D. nanus* has a much larger composite muscle scar and a broader visceral area with the central muscle scar farther from the median line.

One of the types of *D. nanus* is the interior of a ventral valve (Pl. LIII, fig. 2), on which there is a subtriangular depression (c) that appears to have been the path of advance of the areas, on each side of the median space, in which the central muscle, and the middle and outside

lateral muscles, were attached. Another shell from the Bighorn Mountains shows something of the same character (Pl. LIII, fig. 11).

The area of the ventral valve is short, and divided midway by a shallow pedicle furrow; area of dorsal valve unknown.

The exterior of the shell appears to be smooth and slightly polished, except for fine concentric striae and lines of growth and what appear to be scattered punctae.

The average size of the adult shells is from 3 to 4 mm., the length and width usually being nearly the same.

The exact horizon of the type specimen is unknown. It occurs in a somewhat friable, purplish sandstone, unlike any beds in the Middle Cambrian Deadwood formation that I met with. The specimens from the limestones of the Bighorn Mountains, etc., appear to belong to the Upper Cambrian.

FORMATION AND LOCALITY.—**Ordovician:** (302v) Sandstones 2 miles (3.2 km.) west of the main summit of Buffalo Fork Peak [St. John, 1877, pp. 468 and 469 and map opposite p. 324 (near station XLIX)], about 25 miles (40 km.) east of Jackson Lake, Uinta County, Wyoming.

Upper Cambrian: (152a) West side of Dry Creek below Pass Creek; and (158a) limestone north of East Gallatin River near Hillsdale; both in the Threeforks quadrangle (U. S. Geol. Survey), Gallatin County, Montana.

(302u) Upper limestone of the Deadwood formation, north of Cheever's ranch, on the summit of the Bighorn Mountains, Wyoming.

Middle Cambrian: (170) Sandstone about 10 miles (16.1 km.) south-southeast of Bald Mountain, Bighorn Mountains; (302m) middle of shale above lower sandstone on Billy Creek in the Bighorn Mountains; (302y) sandstone on Johnson Creek, Bighorn Mountains; and (302b) limestones near Crowfoot Ridge, Gallatin quadrangle (U. S. Geol. Survey), Yellowstone National Park; all in Wyoming.

(302z) Limestone on Mill Creek, near Landusky, Little Rocky Mountains, Chouteau County, Montana.

(355) Sandstones on Red Canyon Creek, southwest side of Black Hills; and (355d) sandstone in the Black Hills; both in South Dakota.

(11j) Basal part of Bonneterre limestone, Mine LaMotte, Madison County; and (11m) drill cores of limestone at horizons 10 and 20 feet (3 and 6 m.) above the Lamotte sandstone, St. Francois County; both in Missouri.

DICELLOMUS PARVUS Walcott.

Plate LXXXIX, figures 11, 11a-d.

Dicellomus parvus WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 315-316. (Described and discussed as below as a new species.)

General form ovate, with the ventral valve subacuminate and dorsal valve broad oval to subcircular. Valves moderately convex. Surface of outer shell dark and polished; it is marked, when not abraded, by fine, clearly defined, concentric striae and occasional lines of growth. The largest ventral valve has a length of 2.5 mm. and a width of 2 mm. The shell is strong but not thick. Shell substance apparently calcareoconchous.

Ventral valve uniformly convex, except that the slopes toward the cardinal margins are more abrupt than elsewhere; apex appears to be marginal. The interior of the valve shows a short, low, median ridge in the center of the visceral cavity; on each side, and a little in front of the end of the median ridge are the trapezoidal areas for the attachment of muscle scars; rather small, composite cardinal muscle scars occur close to the cardinal margins.

Dorsal valve somewhat less convex than the ventral; apex marginal. The interior of the valve shows well-defined composite cardinal muscle scars, a narrow median septum, and a faintly impressed main vascular sinus that curves outward and forward at about one-third the distance from the outer margin to the median septum; the central muscle scars are small and situated back of the center of the valve on each side of a low median swelling on which the median septum occurs; the position of the anterior lateral muscle scars is indicated at the end of the median septum a little in advance of the center of the valve.

Observations.—This minute shell has the generic characters of *Dicellomus politus* (Hall), but it differs specifically in its minute size and the positions of the muscle scars in the dorsal valve.

FORMATION AND LOCALITY.—**Middle Cambrian:** (C6) Thin slabby limestone in the upper shale member of the *Kiulung* group [Blackwelder, 1907a, pp. 37 and 41 (2d list of fossils), and fig. 10 (bed 12), p. 38], 2.5 miles (4 km.) southwest of

Yenchuang, Sintai district, Shantung; and (C32) a fine-grained bluish-black limestone boulder believed to have come from the lower part of the Kisinling limestone [Blackwelder, 1907b, p. 272], collected in river drift 1 mile (1.6 km.) south of Chonpinghien, on Nankiang River, southern Shensi; both in China.

DICELLOMUS PECTENOIDES (Whitfield).

Text figures 48A-B; Plate LII, figures 6, 6a-c.

Obolus pectenoides WHITFIELD, 1875, Rept. Reconnaissance Black Hills of Dakota, by Ludlow, p. 103, unnumbered plate, figs. 1-3. (Described and discussed as a new species.)

Obolus? pectenoides WHITFIELD, 1880, U. S. Geol. and Geol. Survey Rocky Mtn. Region, Rept. Geology and Resources Black Hills of Dakota, by Newton and Jenney, pp. 338-339, Pl. II, figs. 18 and 19. (Described. The specimens represented by figs. 18 and 19 are redrawn in this monograph, Pl. LII, figs. 6 and 6a, respectively.)

Obolella pectenoides (Whitfield), SCHUCHERT, 1897, Bull. U. S. Geol. Survey No. 87, p. 275. (Merely changes generic reference.)

Dicellomus pectenoides (Whitfield), WALCOTT, 1901, Proc. U. S. Nat. Mus., vol. 23, p. 673. (Merely changes generic reference.)

Dicellomus pectenoides (Whitfield), WALCOTT, 1905, idem, vol. 28, p. 316. (Characterized.)

This is the largest shell of the several species of the genus. A ventral valve 9 mm. long has a width of 11 mm. All that is known of the structure of the shell indicates that it was like *D. politus* (Hall) (Pl. LII) and *D. nanus* (Meek and Hayden) (Pl. LIII). This species differs from all other described species by the anterior position of the central muscle scars of the dorsal valve, its larger size, and the thickening beneath the visceral cavity of the ventral valve. Area of ventral valve short and much like that of *D. nanus* (Pl. LIII, fig. 1c). Specimens from Eau Claire, Wisconsin, show a thickening of the shell beneath the visceral cavity of the ventral valve not unlike that of *Elkania desiderata* (Billings) (Pl. LI, fig. 1a). The interior of the dorsal valve is quite dissimilar in the two species.

FORMATION AND LOCALITY.—**Upper Cambrian:** (151a) Limestone in point overlooking Churn Canyon, on the west side of the Bridger Range; and (158) limestone north of East Gallatin River near Hillsdale, Threeforks quadrangle (U. S. Geol. Survey); both in Gallatin County, Montana.

(78a) "St. Croix sandstone" in the topmost quarry on Mount Washington, near Eau Claire, Eau Claire County; and (100) "St. Croix sandstone" near Menomonie, Dunn County; both in Wisconsin.

Middle Cambrian: (355b) Sandstone in the Deadwood formation on Castle Creek, on the west side of the Black Hills; and (164) sandstone in the Deadwood formation in the cliffs on the east side of the valley near Deadwood, Black Hills; both in South Dakota.

(355c [Whitfield, 1875, p. 103]) Sandstone on French Creek, Black Hills, South Dakota.

DICELLOMUS POLITUS (Hall).

- Dicellomus politus* (Hall), WALCOTT, 1905, idem, pp. 316-318. (Described and discussed as below, although some changes and additions have been made.)

Dicellomus politus (Hall), GRABAU and SHIMER, 1907, North American Index Fossils, vol. 1, pp. 189-190, fig. 224, p. 190. (Described. The three figures in fig. 224 are copied from Hall, 1863, Pl. VI, figs. 17, 20, and 21.)

FIGURE 49.—*Dicellomus politus* (Hall). A, Interior of ventral valve (fsp, pseudospondylium or pedicle plate; l, transmedian scars; j, anterolateral scars; v, visceral cavity; vs, main vascular sinuses). B, Posterior portion of the interior of a ventral valve, showing a strongly developed area (fsp, pseudospondylium or pedicle plate; a, inside section of area; f, flexure line; a', outside section of area).

The specimens represented by figures 49A and 49B are from Locality 79s, Upper Cambrian "St. Croix sandstone" at Hudson, Wisconsin (U. S. Nat. Mus. Cat. Nos. 51917a and 51917b, respectively). The same figures are reproduced on page 314.

marked feature of the species. The radiating striae may be uniform in size, or with 4 to 6 very fine striae between two stronger elevated striae. Inner surface smooth to the eye, but a strong lens shows that it is finely punctate, with exceedingly fine, irregular, raised lines all over the surface. The intermediate layer is more coarsely and irregularly punctate.

The shell is thick, and is built up of a thin, scabrous, outer layer, a middle layer made up of several highly polished lamellae, and a thin inner layer. The numerous inner lamellae are oblique to the outer surface over much of the shell, and thus give it thickness. Shell substance calcareoconchous. The usual length of the ventral valves from Wisconsin is about 6 mm., width 5 mm., with the same width and length for the dorsal valve. Specimens from the Black Hills average a trifle larger than those from Wisconsin.

Ventral valve with a uniform convexity over the central portions, from which the surface slopes gently to the margins. Apex nearly if not quite marginal. Casts of the interior indicate a short cardinal area that extends out on the cardinal margins of the shell and appears to merge into the margins. On each side of the pedicle furrow a thin plate or shelf (sh) extended into the valve on the plane of the margins of the shell. Some of the casts indicate that these

plates had a projecting boss or tooth that articulated in a rude manner with the depressions on the posterior, flattened, inner margin of the dorsal valve. If this interpretation is correct the teeth and plates correspond to the teeth and dental plates of the articulate brachiopods and the plates may mark the beginning of a spondylium.

A number of interiors from Hudson, Wisconsin, show a concave plate in the pedicle furrow, the edges of which rise above the plane of the cardinal area; this plate is evidently the beginning in *Dicellomus* of the pedicle tube, as shown in *Obolella* (Pl. LV, figs. 1e, 1f, and 1h). In some shells the plate appears to extend into the shell beyond the anterior margin of the cardinal area and it then has the appearance of a small spondylium. I think, however, that it is only the secretion of shelly matter about the pedicle and not connected with the development of a spondylium; the latter is indicated by the extension of the toothlike processes already referred to.

The posterior lateral, transmedian, and anterior lateral muscles were undoubtedly attached within the area of the composite scar (cl) (Pl. LII). The visceral area and posterior portions of the main vascular sinuses are well outlined, but no muscle scars or details of the vascular system have been preserved in the material studied.

Dorsal valve most convex back of the center. Apex marginal. The interior of the valve shows shallow depressions in the flattened posterior margin (a) that suggest dental cavities for the reception of the dental projections of the ventral valve. The central muscle scars (h) are shown a little back of the center of the valve, where a low median ridge bifurcates (Pl. LII, fig. 1i). In some shells a sharp median septum is shown, also narrow main vascular sinuses.

Observations.—The reference to this species of the specimens from the siliceous shale at Helena is rather doubtful, as the shells are compressed and distorted. (See Pl. LII, figs. 4 and 4a.)

Shells agreeing with *D. politus* in all points available for comparison occur in the basal, probably Middle Cambrian, sandstone beneath the great limestone series of Arizona. The material is abundant and preserved very much in the same condition as that from the Deadwood formation of the Black Hills of South Dakota.

In sandstones in the basal part of the Upper Cambrian Reagan sandstone in Oklahoma a few shells were found that appear to be identical with *D. politus*. They have the elongate form of that species, which is unknown in any other species of the genus.

In the collections made by the Fortieth Parallel Survey there are specimens so closely resembling *D. politus* that they are identified as such, although the dorsal valve is rather transverse.

Dicellomus politus differs from *D. nanus* (Meek and Hayden) and *D. pectenoides* (Whitfield) in being more elongate, also in the details of the interior markings of the valves. From *D. appalachia* Walcott it differs in interior markings, and, as specimens average, in being more elongate.

FORMATION AND LOCALITY.—Upper Cambrian: (82b) "St. Croix sandstone" along the railroad track near Taylors Falls, Chisago County; (97 and 97x) "St. Croix sandstone" at Reads Landing, foot of Lake Pepin, Wabasha County; (339i) [Owen, 1852, desc. of Pl. IB] sandstones of F1b of Owen's section, below Mountain Island, in Mississippi River, nearly opposite the old mouth of Black River; and (98a) "St. Croix sandstone" at Marine Mills, on St. Croix River, Washington County; all in Minnesota.

(78a) "St. Croix sandstone" in the topmost quarry on Mount Washington, near Eau Claire, Eau Claire County; and (98 and 98x) "St. Croix sandstone" near Eau Claire, Eau Claire County; (79s) "St. Croix sandstone" in bluff near Hudson, St. Croix County; (328c) "St. Croix sandstone" at Alma, Buffalo County; (83) "St. Croix sandstone" near Trempealeau, Trempealeau County; (100a) "St. Croix sandstone" at Ettrick, Trempealeau County; (80) "St. Croix sandstone" 0.66 mile (1.1 km.) southwest of the railway depot, Menomonie, Dunn County; and (100) "St. Croix sandstone" near Menomonie, Dunn County; all in Wisconsin.

(128a) Shales on the Louisville and Nashville Railroad, 1.5 miles (2.4 km.) southeast of Cog Hill, near the line between Polk and McMinn counties, Tennessee.

(9x) Sandstones lying between beds of quartzite underlying the 300 feet of limestone at the top of the Reagan sandstone, SW. $\frac{1}{4}$ sec. 17, T. 4 N., R. 12 W., about 11 miles (17.7 km.) northwest of Fort Sill, Comanche County, Oklahoma.

Upper? Cambrian: (358a) Siliceous limestone on Ash Creek, in Pinal County, Arizona.

Middle Cambrian: (84 and 84f) "St. Croix sandstone" at Dresbach, opposite the mouth of Black River, Winona County; (339e) "St. Croix sandstone" on Mountain Island, in Mississippi River, just above the mouth of Trempealeau River; and (84s) "St. Croix sandstone" near Dakota, Winona County; all in Minnesota.

(79x) "St. Croix sandstone" near the flour mill on Beaver Creek, north of Galesville; and (328g) "St. Croix sandstone," Wisconsin shore of Mississippi River, near Trempealeau; both in Trempealeau County, Wisconsin.

(167) Sandstone beneath limestone and resting on pre-Cambrian "slates, schists, and pegmatites" in bluff 9 miles (14.4 km.) west of Custer, Black Hills; (355e) sandstone in the central part of the Black Hills; and (355) sandstones in Red Canyon ^a Creek, southwest side of the Black Hills; all in South Dakota.

(11m) Drill cores of limestone in the Bonnetterre limestone at horizons 10 and 20 feet (3 and 6 m.) above the Lamotte sandstone, at Flat River, St. Francois County, Missouri.

(329b) Thin-bedded limestone collected by the Wheeler Survey in Utah.

(5k) Limestone in Meagher County, on the road to Wolsey, about 1 mile (1.6 km.) south of the divide at the head of Sawmill Creek, and 8 miles (12.8 km.) south of Neihart, Little Belt Mountains quadrangle (U. S. Geol. Survey), Cascade County; (302k) limestone near Gallatin, Threeforks quadrangle (U. S. Geol. Survey), Gallatin County; (302s) ^b dark siliceous shale in a quarry in Last Chance Gulch, south slope of Mount Helena, 1.5 miles (2.4 km.) south of Helena, Lewis and Clark County; and (340f) lowest beds exposed at the mouth of Bear Creek, Little Belt Mountains; all in Montana.

DICELLOMUS PROLIFICUS Walcott.

Plate LXXXIX, figures 10, 10a-b.

Dicellomus prolificus WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 3, p. 77, Pl. VIII, figs. 3 and 3a. (Characterized and discussed as below as a new species. Figs. 3 and 3a are copied in this monograph, Pl. LXXXIX, figs. 10 and 10b, respectively.)

This species differs from *Dicellomus politus* (Hall), to which it appears to be most nearly related, by the greater convexity of the ventral valve, its higher umbo, and, in most shells, a greater narrowing toward the apex. The dorsal valve differs from that of *D. politus* in being more rounded on the cardinal margins. It is also to be noted that no traces of muscle scars or vascular markings have been observed on many interiors and casts of the interior of the valves, while in *D. politus* they are prominent on most casts and often on the interior of the valves. The range of outline of the valves of *D. politus* might include those of *D. prolificus*, but the convexity of the ventral valve and the smooth interior seem to distinguish the latter species.

Great numbers of the separated valves occur in several thin layers of gray limestones near the summit of the cliffs on the south side of Marjum Pass.

FORMATION AND LOCALITY.—**Middle Cambrian:** (10z) About 2,900 feet (884 m.) above the Lower Cambrian and 1,500 feet (457.2 m.) below the Upper Cambrian in the central part of the limestone forming 1a of the Marjum limestone [Walcott, 1908f, p. 179], in the long cliff about 2 miles (3.2 km.) southeast of Marjum Pass [Walcott, 1908f, Pls. XIII and XV], House Range, Millard County, Utah.

DICELLOMUS sp. undt. Walcott.

Plate LII, figures 7, 7a.

Dicellomus sp. undt. WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 319. (Mentioned as below as a possible new species.)

A single specimen of a ventral valve very much like that of *Dicellomus appalachia* (Walcott) occurs with material from the *Paradoxides forchhammeri* zone at Andrarum. A series of specimens would probably prove that it is the representative of an undescribed species.

FORMATION AND LOCALITY.—**Middle Cambrian:** (3101) *Paradoxides forchhammeri* zone at Andrarum, 20 miles (32.2 km.) northwest of Simrishamn, Province of Christianstad, Sweden.

^a Some of the specimens are labeled as from Redwater Canyon and some as from Red Canyon Creek, the former locality being given by Whitfield [1882, p. 340].

^b The specimens from this locality are somewhat doubtfully referred to this species. (See Pl. LII, figs. 4 and 4a.)

Superfamily KUTORGINACEA Walcott and Schuchert.

Family KUTORGINIDÆ Walcott and Schuchert.

Genus KUTORGINA Billings.^a

- Kutorgina* BILLINGS, 1861, Geol. Survey Canada, Paleozoic Fossils, vol. 1, p. 9, footnote. (Characterized and discussed as a possible new genus; see below for copy.)
- Kutorgina* BILLINGS, 1861, Report on the Geology of Vermont, vol. 2, p. 948, footnote. (Copied from preceding reference.)
- Kutorgina* BILLINGS, 1862, Report on the Economic Geology of Vermont, by Hager, p. 220, footnote. (Copied from preceding reference.)
- Kutorgina* Billings, DAVIDSON, 1868, Geol. Mag., vol. 5, p. 312. (Merely questions genus.)
- Obolella* (*Kutorgina*) (Billings), DALL, 1870, Am. Jour. Conchology, 2d ser., vol. 6, pt. 2, pp. 154 and 163. (Described.)

(Copies Walcott, 1886b, pp. 101-102, on pp. 91-92, and describes and discusses genus, including species now referred to *Micromitra*, *Micromitra* (*Iphidella*), *Micromitra* (*Paterina*), *Protorthis*, and *Billingsella*, as well as those referred to *Kutorgina*.)
- Kutorgina* Billings, HALL and CLARKE, 1892, idem, p. 183. (Discusses generic relations; see the seventh reference in the synonymy of *Botsfordia pulchra*, p. 607.)
- Kutorgina* Billings, WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 306-308. (Original characterization, Billings, 1861b, p. 7, copied and genus described and discussed essentially as below.)
- Kutorgina* Billings, GRABAU and SHIMER, 1907, North American Index Fossils, vol. 1, p. 209. (Described.)
- Kutorgina* Billings, WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 4, Pl. XI, and pp. 142 and 145. (Classification of genus.)

Billings [1861b, p. 9] proposed the genus *Kutorgina* in a footnote accompanying the description of the type species *K. cingulata*. He says:

Since the above was written I have examined many casts of the interior of this species, and am inclined to the opinion that it is generically distinct from *Obolella chromatica*. From the very considerable elevation of the beak the dorsal valve must have an area and probably a foramen. In one specimen there are two large oval impressions faintly impressed, but still distinctly visible. There is no trace of the lateral scars, and the form, notwithstanding the characters of the surface, conveys the idea of an *Orthisina*. Should, upon further examination, my suspicions turn out to be well founded, I shall call the genus *Kutorgina*, after the celebrated European naturalist, Kutorga.

From present information of the genus the following diagnosis is prepared:

Shells inequivalve, transverse or elongated. Ventral valve convex, with apex marginal or incurved over the pseudo-area; cardinal area rudimentary, without any delthyrium or well-defined pseudodeltidium; the latter usually extends one-half the distance from the apex to the plane of the posterior margin of the valve; interior of ventral valve with well-defined main vascular sinuses, with a visceral area between the sinuses. Dorsal valve flat or slightly convex, rising to a small, elevated umbo; apex marginal and usually pointing upward; cardinal area

^a The synonymy for this genus does not give a complete record of the various genera under which the species now included in *Kutorgina* were formerly placed; it gives only those references in which the genus is discussed or described. To complete the record the following mere generic references are listed:

Lingula Bornemann [1891, p. 439].
Kutorgina Bornemann [1891, p. 440].
Orthis? Tate [1892, p. 185].
Kutorgina Frech [1897, Pl. I A, figs. 6a-b].

Kutorgina von Toll [1899, p. 26].
Kutorgina Matthew [1899a, p. 189; 1899d, p. 98].
Kutorgina Walcott [1901, p. 695].

short, rudimentary, and without well-defined pseudodeltidium. Interior of ventral valve with median septum between the central and posterolateral muscle scars.

Observations.—The short cardinal areas of the valves leave a broad open space between them for the passage of the pedicle. The areas are more than reflected posterior margins of the valves, as they have transverse lines of growth and a suggestion of a pseudodeltidium. These features are more rudimentary than in *Micromitra*. *Kutorgina* includes the larger calcareous shells, and *Micromitra* the somewhat more specialized, smaller, corneous shells. The exterior form of the valves of *Kutorgina* suggest *Nisusia festinata* (Billings), with which the type species, *K. cingulata* (Billings), is associated in Vermont and at Bic Harbor.

The genus was named in honor of Kutorga.

KUTORGINA CINGULATA (Billings).

- Kutorgina cingulata* Billings, WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 308–309. (Described and discussed essentially as below, with the exception of the notes and figures on the shell structure.)
- Kutorgina cingulata* von Toll, WALCOTT, 1905, idem, p. 309. (Species and locality mentioned.)
- Kutorgina cingulata* (Billings), GRABAU and SHIMER, 1907, North American Index Fossils, vol. 1, p. 209, fig. 246. (Described. The three figures of fig. 246 are copied from Walcott, 1886b, Pl. IX, figs. 1, 1a, and 1b.)

General form transversely or longitudinally oval; biconvex, with the ventral much more convex than the dorsal valve. Surface marked by concentric lines and ridges of growth and the edges by imbricating lamellæ of growth. Shell substance calcareous and fibrous. The shell is formed of a thin, dark, compact outer layer and a thick, laminated, calcareous inner layer. It is possible that the thin outer layer is chitinous, but it does not appear to be so.

The L'Anse au Loup and Bic Harbor shells average about 15 mm. long by 17 mm. in width. At the locality near Swanton, Vermont, ventral valves occur 24 mm. in length and 30 mm. in width, and one large dorsal valve is 20 mm. in length with a width of 30 mm.

Ventral valve in young shells moderately convex, becoming more and more convex with increase in size and age; in young shells the slope from the front margin to the apex is nearly straight, and the apex terminates at the posterior edge of the valve above the more or less elevated pseudo-area; in old shells the curvature from the front to the apex is nearly a semicircle, and the apex terminates in a pointed beak overhanging the pseudo-area; a mesial sinus, of varying strength, occurs on many shells, and in others it is entirely absent; the area is concave on the outer parts; toward the center it becomes slightly flattened or convex and thus forms a very rudimentary pseudodeltidium; it extends beneath the apex at an angle of about 45° to the plane of the margins of the valve; the pseudo-area extends about one-half the distance from the apex to the plane of the valve and arches gently from the lateral extremities to the center.

A partly exfoliated shell shows four dark lines radiating forward from the umbo and two near the sides that may have something to do with the muscle scars or vascular sinuses.

FIGURE 50.—*Kutorgina cingulata* (Billings). A, Enlargement of a portion of a transverse section of an old shell which shows its laminations and the peculiar manner of growth ($\times 30$). B, C, Vertical sections of an old shell, showing the imbricated manner of growth of the outer thin dark layer ($\times 30$). This outer layer is not preserved in the specimen represented by A.

The specimens from which these sections were made came from Locality 25a, near Swanton, Vermont (U. S. Nat. Mus. Cat. Nos. 15337f, 15337g, and 15337h, respectively).

I thought so in 1886 [1886b, p. 103] but am not sufficiently confident of it now to state it as a settled conclusion. Fine punctæ occur on the inner layer of the shell; also numerous radiating lines about one-half millimeter apart.

Dorsal valve gently convex in young shells; with increase in size the umbo becomes more elevated and the apex points upward or terminates at the union of the pseudo-area and the upward slope of the shell on the umbo; in some shells there is a tendency for the valve to become slightly concave in the space between the margins and the elevated umbo; the area of the valve is narrow and with little character; on some shells it slopes beneath the apex, and on others it slopes backward forming a low angle with the surface of the valve; the interior of the dorsal valve shows a median septum with two central scars (h) and the anterolateral scars (j) (Pl. V, fig. 1h); numerous small vascular canals radiate from the central concave area toward the flattened anterior and lateral half of the valve; a cast of the interior (Pl. V,

fig. 1d) shows two vascular canals radiating forward from near the apex. Radiating lines occur on the interior of the same character as those of the ventral valve.

Observations.—Since writing on this species in 1886 I have collected specimens showing the character of the areas of the valves and also obtained further information relative to the interior of the dorsal valve. The rudimentary areas are less advanced in development than those of *Micromitra*, and the muscle scars of the dorsal valve are much like those of *Obolella* and *Obolus*.

The presence of rudimentary teeth in *Kutorgina cingulata* is very difficult to demonstrate by actual observation, owing to the character of the matrix in which the specimens occur. That articulating processes are present, however, is indicated by the fact that in a relatively small collection thirty of the valves are united, and the fact that the dorsal valve is rarely in any other position than that in which it would be if teeth in the ventral valve held it in its normal position. In only a few of the specimens have the valves slid or turned either way, as they frequently do in the inarticulates.

The specimens from Bic Harbor and east of Swanton, Vermont, are better than those from the type locality at L'Anse au Loup, so I have selected material from these localities for illustration, with the exception of a dorsal and ventral valve. Many of the Vermont shells are larger and more fully developed, but specimens of the same size as those from L'Anse au Loup and Bic Harbor are identical in the characters available for comparison.

FORMATION AND LOCALITY.—**Lower Cambrian:** (392a) Limestones at L'Anse au Loup, on the north shore of the Straits of Belleisle; and (3921)^a arenaceous limestone at Point Amour, Straits of Belleisle; both in Labrador.

(20) Limestone boulders in conglomerate, on shore at east entrance to harbor at Bic, Rimouski County, Quebec, Canada.

(25a)^b Limestone on the Hall (Donaldson's) farm, 2 miles (3.2 km.) east of Swanton; and (319m) shales of No. 6 of the section at Parker's quarry [Walcott, 1891b, p. 278], near Georgia; both in Franklin County, Vermont.

(1v) Shales of No. 3 of the Silver Peak Group, Barrel Spring section [Walcott, 1908f, p. 189], 3 miles (4.8 km.) north of Valcalda Spring and 4 miles (6.4 km.) west-northwest of the Drinkwater mine, Silver Peak quadrangle (U. S. Geol. Survey), Esmeralda County, Nevada.

(35f) About 300 feet (91 m.) below the Middle Cambrian in the limestone forming 6 of the Mount Whyte formation [Walcott, 1908c, p. 242 (11)] just above the tunnel on the north shoulder of Mount Stephen, about 3 miles (4.8 km.) east of Field, British Columbia, Canada.

(347 [von Toll, 1899, p. 27]) Near Tschurskaja Station, on Lena River, Siberia.

KUTORGINA GRANULATA Matthew.

Plate V, figures 5, 5a-c.

Kutorgina granulata MATTHEW, 1899, Bull. Nat. Hist. Soc. New Brunswick, vol. 4, pt. 3, No. 18, p. 189, Pl. I, figs. 2a-d. (Characterized and discussed as a new species. The specimens represented by figs. 2a, 2b, and 2c are redrawn in this monograph, Pl. V, figs. 5 and 5a, 5c, and 5b, respectively.)

Kutorgina granulata MATTHEW, 1899, Trans. Roy. Soc. Canada for 1899, 2d ser., vol. 5, sec. 4, No. 4, p. 98, Pl. V, figs. 2a-d. (Described and discussed. Figs. 2a-d are copied from figs. 2a-d of the preceding reference.)

The description by Matthew [1899e, p. 98] follows:

Shell substance calcareous. Hinge-line straight, somewhat shorter than the full width of the shell; lateral margin straight near the hinge; front margin broadly rounded.

Ventral valve convex, the umbo considerably elevated, the posterior third of the shell somewhat more tumid than the rest; lateral angles somewhat flattened. The area appears to have a deltidium, about one-fifth as wide as the length of the hinge-line; this line, when viewed from behind, appears to be bent up in the middle. *Interior:* On the posterior half there are a number of low vascular ridges; two of these inclose a median groove, which extends to within a third of the front of the valve; there are about three other ridges on each side. These ridges are most distinct near the umbo, and about three or four are found in the space of 1 millimeter.

The dorsal valve is flatter, and has the umbo depressed to the cardinal line, and the sides of the valve toward the hinge much flattened. *Interior:* There is a median septum extending about one-third of the length of the valve, and faintly indicated for another third to a point where there is a small pit on the inner surface of the valve; and there are also radiating lines as in the ventral valve, but more numerous.

The surface is minutely granulated. On the somewhat tumid posterior third of the valve concentric striæ are faintly visible, but they become distinct on the anterior part, and there are very fine radial lines, giving to the summit

^a These specimens are in the collections of the Geological Survey of Canada.

^b The species also occurs in Locality 319e.

of the intervening ridgelets a beaded appearance; at certain intervals stronger concentric striæ of growth show on the surface of the shell; there are about five or six of these on its surface.

Length, 4 mm.; width, 6 mm.; depth of the ventral valve, 1.5 mm.

This species is smaller than *K. cingulata* and differs in its ornamentation.

Observations.—This little shell occurs in reddish limestone beneath a shaly band in which I found fragments of *Olenellus*. Except for size it is much like *Kutorgina cingulata* (Billings) in its general aspect. It differs in the details of surface ornamentation and interior radiating lines.

The form owes its specific name to its granulated surface.

FORMATION AND LOCALITY.—Lower Cambrian: (314b [Matthew, 1899e, p. 97]) Limestone of the "Etcheminian series," at Smith Sound, Trinity Bay, Newfoundland.

KUTORGINA PECULIARIS (Tate).

Plate V, figure 2.

Orthis (?) peculiaris TATE, 1892, Trans. Roy. Soc. South Australia for 1892, vol. 15, pt. 2, pp. 185-186, Pl. II, fig. 5. (Described as a new species; see below for copy. The specimen represented by fig. 5 is redrawn in this monograph, Pl. V, fig. 2.)

The original description by Tate follows:

Transversely subquadilateral, equilateral; hinge-line in the longest anteroposterior [transverse] diameter, straight.

Ventral (?) valve flatly convex, with an abruptly depressed and deeply bilobed ventral margin; the mesial furrow decreases in depth as it ascends to near the umbo; the lateral margins are obliquely arched, nearly straight, forming an angle of about 70° with the hinge-line.

Surface marked by depressed unequal folds of growth.

The author [1892, p. 185] referred to the valve as ventral (?). Its reference to *Kutorgina* identifies the valve as the dorsal. I do not know of a closely related form.

The form owes its specific name to the fact that it seemed to be an unusual representative of the genus to which it was first assigned.

FORMATION AND LOCALITY.—Middle? Cambrian: (315a) Limestone at Parara, near Ardrossan; and (315) limestone at Curramulka; both [Tate, 1892, p. 185] in Yorke Peninsula, South Australia.

KUTORGINA PERUGATA Walcott.

Plate V, figures 3, 3a-e.

Kutorgina perugata WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 310. (Described and discussed essentially as below as a new species.)

General form ovate, biconvex. Surface marked by concentric lines of growth and more or less strong concentric corrugations. The outer surface is ornamented by a fine network of oblique depressed lines that leave minute rhomboidal elevations between them that look like fine papillæ under a moderately strong magnifier, and the cast of the surface has much the same appearance in a transverse light. Shell substance calcareous.

A large ventral valve has a length of 14 mm., width 16 mm. A dorsal valve 11 mm. in length has a width of 14 mm.

The ventral valve is strongly convex in adult shells, with the highest point near the umbo or at the apex; the apex terminates at or overhangs a rudimentary pseudo-area that slopes beneath the shell at an angle of 45° to 60° to the plane of the margins of the valve; the pseudo-area is concave and about half the length of the space between the apex and the plane of the valve. Casts of the interior show well defined main vascular sinuses, with the outline of the visceral area between them.

The dorsal valve is transverse, nearly flat in some examples and slightly convex in others. The surface slopes gradually from the margins to near the umbo, where the slope increases and extends to the upward-pointing apex; a rudimentary pseudo-area slopes backward from the apex. In some examples the pseudo-area appears to be little more than a bending over

of the posterior margins of the shell; in others it has the outline of a slightly convex pseudo-deltidium.

Observations.—This species in its reticulate surface ornamentation recalls *Micromitra* (*Iphidella*) *pannula* (White) and *Mickwitzia monilifera* (Linnarsson). In form the young shells are not unlike *Kutorgina cingulata* (Billings). A large, imperfect, ventral valve, 24 by 24 mm., of this genus, was collected by J. E. Clayton from the Cambrian limestone of the Silver Peak district. It may belong to *K. perugata*, and it is so referred for the present. From the shales of the *Olenellus* zone in Silver Canyon, White Mountain Range, a series of compressed specimens was collected. Some of these show a concave pseudo-area on the ventral valve, also strong main vascular sinuses. Some of the shells from the shales of Locality 175 have lost all traces of surface characters, only a faint, smooth impression remaining.

FORMATION AND LOCALITY.—Lower Cambrian: (313i) Limestone collected at long. 117° 20' W., lat. 38° N., in the western part of Esmeralda County, Nevada.

(1v) Shales of No. 3 of the Silver Peak group, Barrel Spring section [Walcott, 1908f, p. 189], 3 miles (4.8 km.) north of Valealda Spring and 4 miles (6.4 km.) west-northwest of the Drinkwater mine; (175)^a shales carrying *Olenellus* on the divide between Clayton and Fish Lake valleys, about 15 miles (24.2 km.) south-southwest of the town of Silver Peak; and (184) shales at the summit of the Silver Peak Range, 10 miles (16.1 km.) southwest of the town of Silver Peak; all in the Silver Peak quadrangle (U. S. Geol. Survey), Esmeralda County, Nevada.

(7) Shaly beds about 1,000 feet (305 m.) above the quartzitic beds, Silver Canyon, White Mountain Range, Inyo County, California.

KUTORGINA SARDINIAENSIS Walcott.

Plate V, figures 4, 4a-c.

Kutorgina cingulata BORNEMANN [not (BILLINGS)], 1891, Nova Acta Acad. Cæs. Leop.-Carol. Germanicæ Naturæ Curiosorum, Bd. 56, No. 3, p. 440, Pl. XIX (XXXIV), figs. 22 and 23. (Described and discussed in German; see below for translation. Figs. 22 and 23 are copied in this monograph, Pl. V, figs. 4b and 4c, respectively.)

Lingula rouaulti BORNEMANN [not SALTER], 1891, idem, p. 439, Pl. XIX (XXXIV), fig. 21. (Characterized and discussed in German. Fig. 21 is copied in this monograph, Pl. V, fig. 4.)

Kutorgina sardiniaensis WALCOTT, 1901, Proc. U. S. Nat. Mus., vol. 23, p. 695. (Merely changes specific reference of Bornemann's *Kutorgina cingulata*.)

Kutorgina sardiniaensis WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 311. (Original description, Bornemann, 1891, p. 440, translated as below and species discussed as below as a new species.)

The original description by Bornemann follows:

Transversely oval, more or less arched, with a straight margin which is a little shorter than the greatest breadth of the shell. Surface shows strong concentric lines of growth.

Found quite commonly in the slates with *Olenopsis* and *Metadoxides* near Canal Grande, and rarely in sandstone with *Archæocyathus* on Punta Pintau. The specimens in the argillaceous shale are always pressed very flat, and are imperfect; in the sandstone, impressions of the outer surface are often found.

Here belongs, perhaps, also the shell designated above as *Lingula rouaulti* (?).

All that is known of the species is represented by the illustrations. It appears to be congeneric with *Kutorgina cingulata* (Billings), but not specifically identical with it.

FORMATION AND LOCALITY.—Middle? Cambrian: (354) Yellowish-brown slates not far from the buildings of Canal Grande; (354b) yellowish sandstone with *Archæocyathus* at Punta Pintau and elsewhere; and (354e)^b slate at Porto Canal Grande; all [Bornemann, 1891, pp. 439 and 440] in the island of Sardinia, Italy.

KUTORGINA sp. undt. Walcott.

Kutorgina sp. undt. WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 311. (Characterized and discussed as below as an undetermined species.)

Ventral valve transverse, moderately convex; length, 6 mm.; width, 8 mm.; pseudo-area short and sloping beneath the apex at an angle of about 45°.

A single cast from a coarse sandstone is all that is known of this species. It may be a young shell of *K. cingulata* (Billings), but the means of comparison do not justify such a reference.

FORMATION AND LOCALITY.—Lower Cambrian: (47a) Sandstone on the southwest side of Sallings Mountain, 2 miles (3.2 km.) east of Natural Bridge, Rockbridge County, Virginia.

^a The species is somewhat doubtfully identified from this locality.

^b Specimens from this locality are in the collections of the United States National Museum.

Family SCHUCHERTINIDÆ Walcott.

Genus SCHUCHERTINA Walcott.

Schuchertina WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 323. (Mentioned as below as a new genus.)

Schuchertina WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 4, Pl. XI, and pp. 142 and 145. (Classification of genus.)

The description of the type species includes that of the genus, as but one species is known.

Type.—*Schuchertina cambria* Walcott.

The generic name is given in recognition of the thorough work that Prof. Charles Schuchert has done on the Brachiopoda.

SCHUCHERTINA CAMBRIA Walcott.

Plate LI, figures 6, 6a-m.

Schuchertina cambria WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 323-324. (Described and discussed as below as a new species.)

Shell subovate, with valves obtusely acuminate, biconvex. Surface marked by concentric lines and striæ of growth and fine radiating striæ. The inner and outer surface of the shells have very fine punctæ, but no traces of punctæ penetrating through the shell have been observed.

The largest ventral valve has a length of 22 mm.; width, 23 mm.; dorsal valve, length, 17 mm.; width, 18 mm. Shell substance calcareous, rather thick on the umbonal region and thin toward the margins.

Ventral valve subacuminate, moderately convex; on some of the larger shells a broad mesial fold and arching of the frontal margins are present; apex terminates at the margin above a triangular opening or delthyrium; area small and within the plane of the margins of the valve; it is attached to the bottom of the valve and divided midway by a very slight pedicle groove; the margins of the delthyrium-like opening sustain an angle of about 45° to the plane of the valve, and the solid area within is at its center nearly on the plane of the valve; the anterior margins of the area extend upward to meet the margins of the shell, thus forming a solid arched area. The interior of the valve is marked by radiating, shallow, narrow furrows that vary in number and strength in different shells; just in front of the area on each side of the median line oval depressions occur, which correspond in position and shape to the diductor muscle scars of the ventral valve of the Billingsellidæ, and they are so interpreted on the figures; traces of the adductor scars are found on each side of the median line. Dorsal valve obtusely acuminate, about as convex as the ventral valve; apex marginal on the broad, low, median arch of the posterior margin; the only trace of an area that has been observed is shown on figure 6j; a broad, shallow mesial sinus and projecting front margin occur on adult shells; the position of the anterior and posterior adductor muscle scars is indicated, also the umbonal thickening in which the diductor muscles were probably attached, as there is no trace of a cardinal process; radiating furrows like those in the ventral valve are strongly marked in adult shells.

Observations.—*Schuchertina cambria* is a shell that, as far as I know, is unique. In its exterior form it suggests a biconvex orthoid genus, and this likeness is further increased by the flabelliform scars of the ventral valve; the smooth surface and solid cardinal areas suggest *Elkania*. It may be that *Schuchertina* is a type derived from some early Cambrian form allied to the Billingsellidæ. Its general aspects appear to affiliate it with the Orthidæ.

FORMATION AND LOCALITY.—**Middle Cambrian:** (5k) Limestone in Meagher County on the road to Wolsey, about 1 mile (1.6 km.) south of the divide at the head of Sawmill Creek, and 8 miles (12.8 km.) south of Neihart, Little Belt Mountains quadrangle (U. S. Geol. Survey), Cascade County, Montana.

Order NEOTREMATA Beecher.

[νέος, young; and τρήμα, perforation.]

Superfamily SIPHONOTRETACEA Walcott and Schuchert.

Family OBOLELLIDÆ Walcott and Schuchert.

Obolella Billings, MICKWITZ, 1896, Mém. Acad. imp. sci. St.-Pétersbourg, 8th ser., vol. 4, No. 2, pp. 116, 121, and 123-126. (Copies the description of the genus as given by Hall and Clarke, 1892c, pp. 66-67, on pp. 123 and 124 and gives a general discussion of the generic relations of *Obolella* and *Obolus*, etc.)

Obolella Billings, GRABAU and SHIMER, 1907, North American Index Fossils, vol. 1, p. 188. (Described.)

Obolella Billings, WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 4, Pl. XI, and pp. 142 and 145. (Classification of genus.)

Generic characters.—Shell subequivalve, moderately convex; dorsal valve more elevated at the umbo than the ventral; longitudinally ovate or oval in outline, with the dorsal valve sometimes transversely oval. Surface marked by concentric striæ of growth and radiating striæ, except in the subgenus *Glyptias*, which has irregular transverse lines crossing the concentric striæ.

Shell substance unknown in an unaltered condition; it is now calcareous but it may have been calcareocorneous as in *Obolus*. Shell structure formed of a thin outer layer with many thin inner layers or lamellæ more or less oblique to the outer layer; the short lamellæ of the anterior portion of the valves are more oblique than the longer lamellæ of the central and posterior portions and lie at the edges in the same plane as the margins of the valves.

Area of the ventral valve rises from the plane of the margins of the valve at angles varying from 10° to 70°; broadly subtriangular when the beak is projecting, otherwise rounded at the posterior margin almost as much as the area of the dorsal valve; the latter is usually on the plane of the margins of the valve and broadly rounded posteriorly; both areas are striated parallel to the base; in the ventral valve a narrow, shallow furrow divides the area midway; the area of the dorsal valve is divided by a narrow, raised, triangular space, bordered on either side by a more or less deeply impressed groove formed by a narrow fold of the area lamellæ; outside of this groove, and between it and the outer flexure fold of the area (f), a depressed triangular space occurs that has led authors to consider it as the scar of the point of attachment of cardinal muscles (Pl. LIV, figs. 1h, 1i). It sometimes occurs that the inner angle of the area of the ventral valve adjoining the pedicle opening projects forward so as to form a toothlike knob that in the cast is shown by a deep indentation beside the cast of the pedicle opening and between the latter and the projecting cast of the undercut beneath the area (Pl. LV, figs. 1f, 1g). Pedicle opening or foramen of the ventral valve cylindrical, broad at the base and tapering to a minute apex; position of the external opening a little in advance of the point of the beak; as indicated by casts of the tube in *O. atlantica* and a specimen of *O. crassa*. The opening varies in proportional size in different species; it is usually marked by rather strong striæ of growth. It extends upward and backward through the shell, very much as does the foramen in *Trematobolus* and *Botsfordia*.

Splanchnocœle ^a of the ventral valve confined to the posterior half of the valve while in the dorsal valve it extends forward to and in some instances beyond the center; in both valves it extends back to the central part of the area which is bounded by the flexure lines (Pl. LIV, figs. 1i, 2g, 2m). Traces of a median septum are shown in the dorsal valve (Pl. LIV, figs. 1h, 1i, and Pl. LV, fig. 1i), but no definite septum has been observed in the ventral valve. A central median ridge of varying degrees of size and length often extends toward the central portion of the dorsal valve; when it is large, a deep rounded groove usually occurs on each side of it on the inner slope of which the central muscle scars may be situated (Pl. LIV, figs. 2k-m). Often the median ridge is practically absent (Pl. LV, figs. 1i, 4a).

The grooves of the main vascular sinuses begin in each valve at the front margin of the area near the median line, and in the ventral valve gradually extend forward and outward toward the front half of the shell where they begin gently to curve inward, terminating toward the front of the valve, the distance and curvature varying in different species (Pl. LIV, figs. 1f, 2g, 2h, and Pl. LV, figs. 1f, 1h, 3c); in the dorsal valve the main vascular sinuses curve out more rapidly (Pl. LIV, figs. 1i, 2m) and are much less prominent; none of the secondary radial canals or the peripheral vascular sinuses have been observed. The course of the parietal scar between the main vascular sinuses is in front of the splanchnocœle in the ventral

^a Using nomenclature of Mickwitz, 1896.

valves (Pl. LIV, figs. 1e, 2g, 2h), also in the same valves it passes closely around the muscle scars situated between the main sinuses and reaches the base of the area in line with the flexure line of the area; in the dorsal valve it closely follows the outside limits of the muscle scars, but it has not been traced across the main vascular sinuses.

The size and position of the pedicle and umbonal muscle scars is unknown, but they are probably similar to those of *Obolus*. The central scars (h) (Pl. LIV, figs. 1h, 2k, 2l) are placed a little distance each side of the median line in the dorsal valve; in the ventral valve they are not separable from the middle and outside laterals, which occur on each side of the front of the visceral area at (c) (Pl. LIV, fig. 2h). The middle and outside laterals of the dorsal valve (l) are blended and lie obliquely outward before the transmedian scars (i). The transmedian scars are close to the base of the area in both valves, and lie in the line of the prolongation of the flexure line of the area. In number and relative position the muscle scars of *Obolella* as far as known are essentially the same as in *Obolus*.

Observations.—The genus *Obolella* has been under discussion by authors for over fifty years. In the original description Billings [1861b, p. 7] noted its resemblance to *Obolus* but claimed that it was distinct on account of the difference in "the arrangement of the muscular impressions." Later [1872c, p. 356] he compared it again with *Obolus*, but having poor illustrations of both *Obolus* and *Obolella* he failed to discover the true position and relations of the muscle scars in either. It was not until after Mickwitz's memoir [1896] on *Obolus* appeared, and the collections of *Obolella* made under my direction during the summer of 1899 were studied, that any correct comparisons could be made. It then became evident that as far as known there was practically no difference in the arrangement of the muscle scars of the two genera, but that there were most essential differences in the cardinal area of the ventral valve. Before working out the fact that the ventral valve was perforated by a pedicle tube or foramen, I was at a loss to find generic difference of value, although I believed that the area of the dorsal valve of *Obolella* indicated differences not readily explained.

The pedicle passage of *Obolus* varies greatly in size and form, but it is always an open furrow. In *Obolella*, it is in the ventral valve a cylindroconical tube, the cardinal area rising from the plane of the margin of the valve beneath the pedicle tube; in the dorsal valve a slightly raised area occupies the place of the broad furrow in *Obolus*.

Obolella is confined to the *Olenellus* or Lower Cambrian fauna. *Obolus*, as now limited, appears in the Lower Cambrian, and has its greatest development in the Middle and Upper Cambrian fauna.

Bicia gemma is associated with *Obolella crassa* both at Bic and Troy, and the species was referred to *Obolella* by Billings [1872a, p. 218]. It differs so radically from *Obolella* in the character of the areas of the valves and the interior markings that it is scarcely necessary to institute comparisons between them. *Lingulella schucherti* is found associated with *Obolella crassa* at Troy, New York.

The interior markings of *Obolella* and *Botsfordia* are quite similar (Pls. LIV and LV, and Pls. LVII and LIX). The same is true of *Trematobolus* (Pl. LXXXIII), but the pedicle opening of *Botsfordia* is above the beak with almost no area beneath, while that of *Obolella* is above a well-defined false area, and that of *Trematobolus* is more in advance of the beak.

OBOLELLA ASIATICA Walcott.

Plate LV, figures 6, 6a.

Obolella asiatica WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 297. (Described and discussed as below as a new species.)

General form broad, oval, with the ventral valve showing a tendency to become bluntly acuminate. Valves gently convex. Surface of shell marked by concentric, raised lines of growth that form the front edge of narrow lamellæ of varying width; the raised lines are highest in front, which gives an imbricated appearance to the surface; fine concentric striæ occur on the interspaces between the raised lines. Shell strong, apparently calcareous.

The specimens occur in a compact, bluish-gray oolitic limestone. None of them show the area or interior of the valves. The reference to *Obolella* is based on the general form and calcareous shell. The shells vary in size from 3 to 5 mm.

Obolella asiatica may be compared with young shells of *O. crassa*. Its broadly elliptical form and slight convexity distinguish it from other species of the genus.

It may be that if material is found showing the interior valves the generic reference will be changed; but with the data now available, the reference is to *Obolella*.

The geological horizon is in some doubt, as the specimens were found in a block of river drift limestone. The associated fragments of trilobites are too indefinite for determination. *Obolella* is a Lower Cambrian genus as far as known, and other blocks of river drift limestone at the same locality contained fragments of *Redlichia*, so the reference of the species is made to the Lower Cambrian. By error *O. asiatica* was included in the list of the Middle Cambrian fossils of China [Walcott, 1905b, p. 5].

FORMATION AND LOCALITY.—Lower Cambrian: (C32') Limestone boulder collected in river drift 1 mile (1.6 km.) south of Chonpinghien, on Nankiang River, southern Shensi; and (C17) ferruginous limestone nodules in the brown sandy shales at the top of the Manto shale [Blackwelder, 1907a, p. 27 (list of fossils at top of page) and fig. 6 (bed 15), p. 25], at Changhia, Shantung; both in China.

OBOLELLA ATLANTICA Walcott.

- Obolella atlantica* Walcott, GORHAM, 1905, idem, Pl. I, figs. 2a-c. (No text reference. Figs. 2a-c are copied from Shaler and Foerste, 1888, Pl. I, figs. 2a-c, respectively.)
- Obolella atlantica* Walcott, GRABAU and SHIMER, 1907, North American Index Fossils, vol. 1, p. 188, figs. 222a-d. (Described. Figs. 222a-d are copied from Walcott, 1891a, Pl. LXXI, figs. 1, 1a-c, respectively.)

General form ovate, with ventral valve obtusely acuminate in the uncompressed specimens; dorsal valve nearly circular, with the transverse diameter the greatest in the best preserved shells (Pl. LV, figs. 1h and 1i). Valves moderately convex. Surface of the shell marked by concentric striæ and more or less imbricating lines of growth; fine radiating striæ that are sometimes raised lines strongly mark most shells, although in some instances the striæ are absent, probably from having been worn away by abrasion. When the imbricating lamellæ of the shell are broken the surface has the appearance shown by figure 1c.

The shells from the limestones of Manuels Brook appear to be relatively thick and formed of several layers, the lamellæ being arranged so as to terminate slightly oblique to the outer surface, thus forming the foundation for the imbricating lines of growth. The Smith Point material shows only casts of the outer and inner surfaces, as do most of the specimens from North Attleboro. The thickening of the outer portions of the shell by the growth of the oblique lamellæ forms a strong interior margin which is usually flat (Pl. LV, figs. 1a and 1h), but it is sometimes oblique to the plane of the edges of the valves (fig. 1a). The ventral valves average about 5 mm. in length, the largest is 8 mm.; the dorsal valve is a little shorter than the ventral.

The area of the ventral valve is low and rises from the edge of the valve to meet the beak at an angle of 30° to 45° ; it extends well out on the cardinal slopes before merging into them; a narrow furrow divides it midway.

The anterior margin of the area adjoining the false pedicle furrow forms a tooth or knob-like projection (Pl. LV, fig. 1e) that forms a deep recess next to the cast of the pedicle tube in the casts of the interior of the ventral valve (fig. 1f). The surface of the area is marked by fine transverse striae. On each side of the pedicle tube there is a strong undercut which in the cast is replaced by a toothlike projection. The area of the dorsal valve extends nearly as far out on the cardinal slopes as that of the ventral; it is marked midway in the cast by two ridges that converge toward the median line at the posterior margin; these ridges represent furrows such as occur on the areas of some species of *Obolus* and *Lingulella* at the side of the flexure lines (*Lingulella acutangula* (Roemer), Pl. XVII, fig. 1h). They are also present in the dorsal valve of *Obolella chromatica* Billings.

The pedicle tube or foramen is beautifully shown in numerous casts of the ventral valve. When the shells are compressed the cast of the tube rests so nearly on the area that one is led to doubt the existence of shell between the area and the tube. (See Pl. LV, figs. 1f, 1g, 3c.) In uncompressed specimens the cast of the tube extends upward and backward as shown by figure 1h. The cast shows a minute apex and trumpet-shaped base. None of the specimens show the exterior foraminal opening, nor has it been seen in any species of the genus.

FIGURE 51.—*Obolella atlantica* Walcott. View of ventral valve, tipped back to show pedicle opening beneath the area ($\times 4$). (The same specimen is shown in a different position in Pl. LV, fig. 1e.) The specimen is from Locality 50, Lower Cambrian shales at Smith Sound, Trinity Bay, Newfoundland (U. S. Nat. Mus. Cat. No. 51948a).

The strong pedicle furrow shown on the cardinal area in Plate LV, figure 1e, does not exist on the specimen, except as indicated by two faint lines. The true pedicle tube opening is shown beneath the area, as represented in figure 51. This was drawn from the same specimen as that represented in Plate LV, figure 1e.

The muscle scars are not well preserved in the material available for study. The position of the transmedian scars (i) is indicated on each valve; also in the ventral valve the space occupied by the central, middle lateral, and outside lateral muscle scars.

Of the vascular markings the main sinuses of the ventral valve are fairly well shown, also the outlines of the parietal scar (Pl. LV, fig. 1g). The presence of a short median ridge is indicated on a cast of the dorsal valve (fig. 1i).

Observations.—This small but very interesting species is most nearly related to *O. chromatica* Billings. It is nearly the same size, has the same type of shell structure, and probably the same surface characters. It differs in being less convex, in having a more transverse dorsal valve, less elongate ventral valve, and the narrower marginal border on the inside of the shell, as shown by comparing Plate LV, figure 1h, with Plate LIV, figure 1h.

The separated valves occur in immense numbers in the shales above the limestone on Smith Point and they are also abundant in a ferruginous limestone at Manuels. The mode of occurrence of the species is very much like that of *O. chromatica*, of which it appears to be the Atlantic coast province representative; hence the specific name.

FORMATION AND LOCALITY.—**Lower Cambrian:** (50) Just below the Middle Cambrian in shales on Smith Point; and (5n) shales about 275 feet (84 m.) below the horizon of Locality 50 on Smith Point; both in Smith Sound, Trinity Bay, Newfoundland.

(5t) Shale and limestone nodules about 20 feet (6 m.) above the base of the Cambrian, on Redrock Point near Chapple Cove, Hollywood Point; (41) sandstone [see Walcott, 1891b, p. 260, for position in section] on Manuels Brook; (41a) limestone [Walcott, 1891b, p. 260] on the mainland beneath Topsail Head; and (5p) limestone 300 feet (91.4 m.) southeast of the railway station, Manuels; all on Conception Bay, Newfoundland.

(9n and 326e) Dark-purplish siliceous shales on Pearl Street, North Weymouth, Norfolk County; (326f [Burr, 1900, p. 47]) 0.5 mile (0.8 km.) south of North Weymouth, Norfolk County; and (326d) station 2 of Grabau [1900, p. 610], near North Attleboro, Bristol County; all in Massachusetts.

Specimens compared with this species occur at the following locality:

Lower Cambrian: (59m) Weisner quartzite in the Roan iron mine, Bartow County, Georgia.

OBOLELLA CHROMATICA Billings.

Plate LIV, figures 1, 1a-i.

- Obolella chromatica* Billings, WALCOTT, 1899, Mon. U. S. Geol. Survey, vol. 32, pt. 2, p. 446. (Note on generic relations.)
- Obolella chromatica* Billings, WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 313. (Copied from Walcott, 1899, p. 446.)

General form ovate, with ventral valve obtusely acuminate; dorsal valve broadly rounded, with a tendency to become subacuminate in most specimens. Valves rather strongly convex, with the beak of the ventral valve raised above the plane of the posterior margin, but usually below the greatest elevation of the valve. The beak is slightly incurved over the area of the ventral valve, and that of the dorsal valve terminates at the posterior margin, or may be very slightly curved over it.

Surface of the shell marked by concentric striæ and lines of growth and fine radiating striæ. The latter are usually absent either from the exfoliation of the outer layer of the shell, or from having been abraded before the shell was embedded in sediment. Shell rather thick and formed of several layers or lamellæ within a thin outer layer. The outer layer usually adheres to the matrix, and the inner layers have been so replaced by calcareous matter that the shell appears to be solid. In a few examples the individual layers are preserved, and the oblique lamellæ, encircling the anterior portions of the valves, form imbricating lines where the outer layer has been removed. Billings [1861c, p. 947] described the shell as breaking with a granular fracture, and when weathered as having a tendency to fibrous exfoliation, which is true for the specimens in which the original structure is lost.

The area of the ventral valve is usually lower than the greatest elevation of the surface (Pl. LIV, fig. 1a), but it may be as high as any portion of it (fig. 1c); it projects backward at an angle varying from 45° to 70°. Billings states 45° to 60° from material he studied. The area is divided midway by a narrow pseudo-pedicle furrow (p, fig. 1f). The area of the dorsal valve is well defined in the cast (fig. 1g) and much like that of *O. crassa* (Hall) (fig. 2k) and *O. atlantica* Walcott (Pl. LV, fig. 11). The two ridges on the cast that converge toward the posterior margin are broader than in any other species except *O. lindströmi* Walcott (Pl. LV, fig. 4a).

The position of the depressions (a) these ridges filled on the area is shown by figures 1h, 1i; they are triangular areas on each side of a raised, central, triangular space that corresponds in position to the pedicle furrow in species like *Lingulella* (*Lingulepis*) *acuminata* (Conrad) (Pl. XLII, fig. 2a). In *Obolus apollinis* this portion of the area is sometimes slightly elevated, with a depressed furrow on either side (Pl. VII, figs. 6, 7). The cast of the cylindroconical pedicle tube or foramen has been observed in a cast of the interior of the ventral valve (fig. 1e). This is best seen in *Obolella atlantica* (Pl. LV, figs. 1f, 1g, 1h). The external foraminal opening has not been observed.

The muscle scars are unfortunately not well preserved. The general position of the transmedian and anterior laterals is shown in the ventral and dorsal valves (i, j, Pl. LV, figs. 1f, 1g); the centrals (h) and the anterior laterals (j) in the dorsal valve (fig. 1h). The position of the central, middle, and outside lateral muscle scars is indicated in the ventral valve by the outline of the visceral cavity (v) as shown on figures 1e, 1f, but no individual scars can be determined. The outside and middle laterals of the dorsal valve are merged with the transmedian in all the specimens showing them at all; this is undoubtedly owing to the poor preservation of the specimens.

The main trunks of the vascular sinuses are fairly well shown in both valves; also the outline of the parietal scar between the sinuses. A rather strong median ridge occurs in the posterior half of the dorsal valve on which the small anterior lateral muscle scars are situated (Pl. LIV, figs. 1g-i).

Observations.—When the validity of the genus *Obolella* was attacked [Hall, 1867, p. 110] Billings restudied this, the type species, and gave [1876, p. 176] an elaborate description of all the characters he could determine. Through the kindness of the director of the Geological Survey of Canada and of Prof. J. F. Whiteaves, I have had the opportunity of studying the material in the Canadian Survey collection. Prof. Alpheus Hyatt also sent me specimens he collected at L'Anse au Loup and I found some very good specimens in a small collection in the United States National Museum, that were not accessible when I illustrated the species in 1886 [1886b, Pl. XI, figs. 1, 1a-b] and 1891 [1891a, Pl. LXXI, figs. 2, 2a-b]. Among the new characters discovered are: (a) the narrow pseudo-pedicle groove; (b) the cast of the cylindroconical pedicle tube or foramen; (c) the character of the area of the ventral valve; (d) the vascular impressions of the interior of the ventral valve; these taken in connection with the features shown by *O. atlantica* Walcott establishes the genus *Obolella* as distinct from *Obolus* and *Dicellomus*.

The species *O. chromatica* Billings is about the same size as *O. atlantica*, but it differs in outline, convexity, and details of the areas of both valves. I know of no other species with which it is necessary to compare its specific characters. It is in association with *Olenellus thompsoni* and other fossils characteristic of the upper portion of the Lower Cambrian fauna in the Gulf of St. Lawrence and the Lake Champlain region. The bits of limestone brought from Labrador show great numbers of the separated valves, indicating that they occur in large numbers in one or more layers.

Von Toll [1899, p. 27, Pl. I, fig. 27] illustrates a specimen from 3 miles (4.8 km.) beyond Bestjachskaja station, on Lena River, Siberia, which he compares with *Obolella chromatica* Billings. It is too imperfect to determine with any degree of certainty what it may be.

FORMATION AND LOCALITY.—Lower Cambrian: (392a) Limestones at L'Anse au Loup, on the north shore of the Straits of Belleisle; (392c [Billings, 1872a, p. 218]) at the Straits of Belleisle; and (3921) arenaceous limestone at Point Amour, Straits of Belleisle; all in Labrador.

(314f) Limestone of B7 of the section at Bonne Bay [Walcott, 1891b, p. 255], Newfoundland.

(338p) Sandy limestone one-fourth mile (0.4 km.) northwest of schoolhouse No. 7 in Greenwich, Cambridge quadrangle (U. S. Geol. Survey), Washington County, New York.

OBOLELLA CRASSA (Hall).

Text figure 14, page 299; Plate LIV, figures 2, 2a-n.

- Obolella crassa* (Hall), WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 321. (Discussed.)
- Obolella crassa* (Hall), GRABAU and SHIMER, 1907, North American Index Fossils, vol. 1, pp. 188-189, figs. 222e-g, p. 188. (Described. Figs. 222e-g are copied from Walcott, 1886b, Pl. X, figs. 1, 1e, and 1c, respectively.)

General form ovate to suborbicular, with the ventral valve bluntly acuminate in some examples. Considerable variation in outline occurs, as is shown by Plate LIV, figures 2, 2a, 2b of the ventral valve, and 2k, 2l of the dorsal valve. Valves moderately convex, with the beak of the ventral valve depressed below the greatest elevation of the surface and slightly curved over the low area; the beak of the dorsal valve terminates at the posterior margin.

Surface of the shell marked by rather strong, concentric striæ and lines of growth that interrupt the continuity of fine radiating lines; it is rarely that the surface is well preserved; usually the shells are smooth as though they had been abraded. Shell rather thick, and formed of several layers or lamellæ that are more or less oblique to a thin outer layer; the short oblique lamellæ encircling the anterior portion of the valves form imbricating lines when the outer surface is removed (Pl. LIV, fig. 2b). Very few shells show the shell structure; usually the calcareous matter has so far replaced the original shell that there is only a solid calcareous, granular, or calcite shell, as shown by the broken section (fig. 2f). The weathered surface often has a fibrous appearance similar to that of the shell of *Obolella chromatica* Billings.

The area of the ventral valve is usually short, but it varies considerably in this respect (Pl. LIV, figs. 2g, 2h, 2j). It overhangs the posterior margin at an angle varying from 45° to 70° and extends well out onto the cardinal slopes; fine striæ of growth parallel to the margin cross the area and pass into and across the central furrow; a narrow furrow divides the area midway (Pl. LIV, figs. 2g, 2h, and 2j). The specimen represented by figure 2h has a rounded cardinal area and a very shallow median furrow; a small pedicle opening is outlined beneath the rounded area, but it is not shown in the illustration. A tendency of the inner point of the area next to the furrow to thicken and project forward into the cavity of the shell is found in several specimens, but it is not as pronounced as in *Obolella atlantica* Walcott. The area

of the dorsal valve is flat and marked midway by a slightly raised triangular space with depressed triangular spaces on each side; what appear to be flexure lines cross the area very much as they do in the area of the dorsal valve of *Obolus apollinis* Eichwald. Pedicle tube or foramen of ventral valve small, cylindroconical. It has been observed in a broken section of the posterior portion of one shell (Pl. LIV, fig. 2n). The external foraminal opening is a little in advance of the extreme end of the beak.

The muscle scars are more clearly shown in *O. crassa* than in any other species of the genus. The transmedians (i) in both valves are near the margin of the area and close to the main vascular sinuses; the outside and middle laterals (l) of the dorsal valve can not be separated, but their position a little in advance and slightly outside of the transmedian is well indicated on the casts of the interior (Pl. LIV, figs. 2k and 2l); the anterior laterals of the ventral valve are shown by figure 2h at j, a little in advance and outside of the transmedian, also in the dorsal valve as small oval scars each side of the median line near the center of the shell; the central scars (h) of the dorsal valve are elongate, oval, and situated on the inner edge of a groove bounding the visceral cavity, about one-fourth of the distance between the anterior lateral scars and the posterior margin of the shell; the central, middle lateral, and outside lateral scars of the ventral valve have not been differentiated; the area (c) in which they should occur (Pl. LIV, figs. 2g and 2h) is clearly outlined in a number of specimens; the pedicle and umbonal scars have not been observed.

The main vascular sinuses of the ventral valve are strongly marked and extend forward well toward the front margin of the shell; they vary in form and position in different shells largely on account of the thickness and manner of deposit of the shell substance. The figures 2g-j illustrate better than any description I can give the character of the sinuses and the principal variations as far as known to me. In the dorsal valve the main sinuses extend farther out from the median line than in the ventral, but they are small and inconspicuous when compared with the latter or with the strongly impressed grooves on each side of the visceral cavity. The latter grooves rise to give the peculiar ridges having the appearance of frog legs that are so strongly marked in the cast of the dorsal valve of *Obolus (Lingulobolus) spissus* (Billings) (Pl. XVI, fig. 2d).

Observations.—In a former paper [1886b, pp. 114–116] I have quoted the descriptions of this species by Hall and Ford. With the material now available and our more detailed information of the genus, it is unnecessary to repeat or to comment on those descriptions or on the slight additions made by myself, except the reference made to *Avicula? desquamata* Hall.

Billings [1861b, p. 7] thought that *Avicula? desquamata* Hall might be referred to *Obolella*, and Ford [1871, p. 33] referred *Orbicula? crassa* Hall to the same genus. Later [1878, p. 128] the latter observer placed *Avicula? desquamata* as a synonym of *O. crassa*, saying:

The species known as *Obolella crassa* of the Troy beds may also be briefly noticed in this connection. It includes the species already widely known under the name of *O. desquamata* from the same locality, this latter, as may be shown, having been founded upon the dorsal valve of the former. The ventral valve is always more acutely pointed at the beak than the dorsal, but beyond this feature there is nothing, so far as I have been able to discover, by which they may be distinguished from each other externally. The surface of each when perfect is both radiately and concentrically striated. As a rule, however, the imbricating edges of the successive layers of growth are the only markings visible.

Obolella crassa is one of the large species of the genus. There is no closely allied species on the American Continent, but *O. mobergi*, of Sweden, may be considered as such in the Scandinavian Cambrian faunas. Some examples of the outer surface of *O. mobergi* resemble *O. crassa*, but a careful comparison of the form and also of the interior of the valves shows striking specific differences (Pls. LIV and LV). The presence of a well-marked median furrow on the area of the ventral valve and a relatively small pedicle tube are noticeable features in *O. crassa*.

Obolella crassa is very abundant in some of the limestone layers interbedded in the siliceous shales at Troy, New York. It also occurs in the limestone conglomerate of the same region. It is associated with the *Elliptocephala asaphoides* fauna in the Hudson Valley, and a similar fauna is found in the limestone boulders of the Bic conglomerate in the St. Lawrence

Valley. I have found no traces of it in the Atlantic province Cambrian formations. Stratigraphically, it is, I believe, the oldest representative of its genus in America.

FORMATION AND LOCALITY.—**Lower Cambrian:** (392c [Billings, 1872a, p. 218]) At the Straits of Belleisle, Labrador.

(56b) Limestone boulder in conglomerate, on the south shore of Orleans Island, below Quebec; (2o) limestone boulders in conglomerate, on shore at east entrance to harbor at Bic, Rimouski County; and (319b) conglomeratic limestones containing *Olenellus?*, at St. Simon; all in Quebec, Canada.

(319k) Calcareous sandstone near the base of the section west of Parker's quarry, on cliff overlooking Lake Champlain, east of Georgia, Franklin County, Vermont.

(2b)^a Limestone just north of Beman Park, in the northeastern part of the city of Troy, Troy quadrangle (U. S. Geol. Survey); (27) even-bedded and conglomerate limestones on the ridge in the eastern suburb of Troy, Troy quadrangle (U. S. Geol. Survey); (338q [Hall, 1847, p. 290]) calcareous beds 2 miles (3.2 km.) northeast of Troy, Troy quadrangle (U. S. Geol. Survey); (27a) reddish sandstone about 1 mile (1.6 km.) east of Lansingburg, north of Troy, Cohoes quadrangle (U. S. Geol. Survey); and (29a) limestone 1 mile (1.6 km.) below the New York Central Railroad depot at Schodack; all in Rensselaer County, New York.

(338o) Shale on Moses Hill, 2 miles (3.2 km.) west of North Greenwich; and (35) limestones 1.5 miles (2.4 km.) north of Bald Mountain; both in the Schuylerville quadrangle (U. S. Geol. Survey), Washington County,^b New York.

(326d) "Station 2" of Grabau [1900, p. 610] near North Attleboro, Bristol County; and (326g [Grabau, 1900, p. 620]) limestones at East Point, Nahant, Essex County; both in Massachusetts.

Specimens that are somewhat doubtfully referred to this species occur at the following localities:

Lower Cambrian: (50a) Sandstone 2 miles (3.2 km.) northwest of York, York County; and (12v) sandstone above the quartzite 1 mile (1.6 km.) west of Fruitville on Little Couestoga Creek, Manheim township, Lancaster County; both in Pennsylvania.

(59m) Weisner quartzite in the Roan iron mine, Bartow County, Georgia.

OBOLELLA CRASSA ELONGATA n. var.

Plate LV, figures 5, 5a.

In the collections from St. Simon there is an oval or elongate ovate form to which it appears to be desirable to give a varietal name. Its surface is marked by stronger concentric lines of growth than usually occur on the less elongate shells of *O. crassa* (Hall), and the valves, especially the dorsal, are much more elongate than those of *O. crassa*. One ventral valve of the latter species from Troy, New York, is nearly as elongate (Pl. LIV, fig. 2a), but it is broader on the posterior half of the shell than those from St. Simon referred to the variety *elongata*.

FORMATION AND LOCALITY.—**Lower Cambrian:** (319b) Conglomeratic limestones containing *Olenellus?*, St. Simon, Province of Quebec, Canada.

OBOLELLA GROOMI Matley.

Text figure 52, page 596.

Obolella (?) *groomi* MATLEY, 1902, Quart. Jour. Geol. Soc. London, vol. 58, pt. 1, pp. 137 and 139, figs. 1-2, p. 137.

(Described and discussed as a new species, see below for copy. Fig. 1 is copied on p. 596 as fig. 52.)

The original description by Matley follows:

Shell oval, moderately convex, about as long as wide, widest toward the front, which is moderately to well rounded. Lateral margins straight or slightly convex, converging posteriorly to form a rounded beak. Hinge-area absent, or not well defined. Sides usually somewhat deflected. Surface covered by about thirty small but well-marked, concentric, rugose ridges. No radial striae. Casts of the interior show nothing but very faint traces of markings.

About 4.5 mm. long by 5 mm. wide. Type in Professor Groom's collection. Other specimens measure:

| Length. mm. | Width. mm. |
|----------------|---------------|
| 7 | 5.5 |
| 5.5 | 5 |
| 4.5 | 4.75 |

^a The species also occurs at Locality 2d.

^b This species also occurs at Locality 2o.

Several specimens of this shell have been collected by Prof. Theodore Groom, in honor of whom the specific name is given. With no knowledge of its internal characters, the generic reference is necessarily provisional, but the species approaches in outline and external characters some American forms of the genus *Obolella*, especially the type species of the genus, *O. chromatica* Billings, of the *Olenellus* zone of Canada, from which, however, it appears to be separated by the form of the beak and the shape of the umbonal region.

FIGURE 52.—*Obolella groomi* Matley.
A, A', Top and side views of a ventral valve. The figures are copied from Matley [1902, p. 137, fig. 1].

There is little to add to Matley's description and observations, except to call attention to the resemblance in general form and surface of this species to the figure of *Obolella crassa elongata* on Plate LV, figure 5. As described and illustrated the species appears to be a true *Obolella*.

FORMATION AND LOCALITY.—Lower Cambrian: (304c)^a "Malvern quartzite" at Raggedstone Hill; and (304d)^a "Malvern quartzite" at Midsummer Hill; both [Groom, 1902, p. 94] in the Malvern Hills, between Herefordshire and Worcestershire, England.

OBOLELLA? LINDSTRÖMI Walcott.

Plate LV, figures 4, 4a.

Obolella lindströmi WALCOTT, 1901, Proc. U. S. Nat. Mus., vol. 23, pp. 674-675. (Characterized and discussed essentially as below as a new species.)

This species differs from *Obolella mobergi* Walcott in the more subacuminate outline of the valves, the surface characters, and the interior of the dorsal valve. The last is well shown by comparing figures 3e and 4a (Pl. LV). Figures 3 and 4 clearly indicate the difference in surface of the two species. The surface of *O. ? lindströmi* is much like that of *Bicia gemma* (Pl. L, figs. 1a and 1d).

The ventral valve (Pl. LV, fig. 4) occurs in a hard gray sandstone of the *Mesonacis torelli* zone, and the cast of the dorsal valve (fig. 4a) is from one of the brown sandstone masses that occur within the gray sandstone at Sularp. I am not sure that the dorsal valve illustrated actually belongs to this species, as it is not associated with the typical ventral valve. It differs from the typical dorsal valves of *O. mobergi* in being more acuminate, and there is no corresponding ventral valve associated with it in the material studied.

I take pleasure in naming the species in honor of Dr. G. Lindström, to whom all paleontologists are deeply indebted for his many fine contributions to the paleontology of the Silurian formations of Scandinavia.

FORMATION AND LOCALITY.—Lower Cambrian: (321v) Gray sandstone of the *Mesonacis torelli* zone at Björkelunda, south of Simrishamn, Province of Christianstad; and (321s) brown sandstone interbedded in gray sandstone at Sularp, near Lund, Province of Malmöhus; both in Sweden.

OBOLELLA MINOR (Walcott).

Plate LIV, figures 3, 3a-d.

Camerella minor WALCOTT, 1890, Proc. U. S. Nat. Mus. for 1889, vol. 12, pp. 36-37. (Described and discussed as a new species.)

Camerella ? minor WALCOTT, 1891, Tenth Ann. Rept. U. S. Geol. Survey, p. 614, Pl. LXXII, figs. 4, 4a-d. (Text copied from preceding reference. Figs. 4, 4a-d are copied in this monograph, Pl. LIV, figs. 3b, 3, 3c, 3d, and 3a, respectively.)

Camerella minor Walcott, HALL and CLARKE, 1894, Nat. Hist. New York, Paleontology, vol. 8, pt. 2, p. 221. (Characterized and discussed.)

Protorhyncha ? minor (Walcott), SCHUCHERT, 1897, Bull. U. S. Geol. Survey No. 87, p. 334. (Generic reference changed and generic relations discussed.)

Obolella minor (Walcott), CLARK and MATHEWS, 1906, Maryland Geol. Survey, vol. 6, 1906, pt. 1, p. 252, Pl. XVI, figs. 13 and 14. (No text reference. Figs. 13 and 14 are copied from Walcott, 1891a, Pl. LXXII, figs. 4a and 4c, respectively.)

General form ovate, biconvex. Surface smooth or marked by concentric lines and varices of growth. Ventral valve subacuminate, moderately convex, with the most elevated portion at the umbo, which curves downward toward the small apex; the posterior or umbonal third

^a Neither Groom [1902, p. 94] nor Matley [1902, p. 137] states which of these localities is the type locality.

of the valve is usually more or less tumid, a ridge of growth separating it from the anterior portion of the shell; area nearly on the plane of the margins of the valve and divided midway by a narrow, deep, pedicle furrow; casts of the interior show that the area formed a shelf on each side of the pedicle furrow. Dorsal valve transversely ovate; a narrow, short area and a slight median ridge are indicated on a cast of the interior.

This shell is small. A large ventral valve measures, length, 7 mm.; width, 6 mm.; a dorsal valve, length, 6 mm.; width, 6.5 mm.

Observations.—The characters of this little shell, as far as they are known, are those of *Obolella*. In my original description I gave an erroneous interpretation to the cast of the interior of the ventral valve. At that time I did not know much of the interior of *Obolella*, and also considered the cast of the space beneath the area beside the pedicle groove as indicating the existence of plates as in *Pentamerus*. In the absence of the shell or fine casts it is impossible to determine conclusively whether a foraminal tube existed, as in *Obolella atlantica* Walcott, or not; one cast indicates that such was the case. The form and long area distinguish this from other species of the genus.

FORMATION AND LOCALITY.—Lower Cambrian: (16f) Sandstone at the mouth of Little Antietam Creek, near Eakles Mills; (47d)^a sandstones 1 mile (1.6 km.) east-southeast of Smithsburg; (47e) sandstone on Observatory Hill, 2 miles (3.2 km.) south of Keedysville; and (47f) sandstone at Eakles Mills, 2 miles (3.2 km.) south of Keedysville; all in Washington County, Maryland.

(32) Sandstone on the south slope of Stissing Mountain, Dutchess County, New York.

(49b) Sandstone 2 miles (3.2 km.) northwest of Emigsville, York County; (49c) sandstone in ridge just north of the railway station in Emigsville, York County; (49d) sandstone 3 miles (4.8 km.) east of Waynesboro, Franklin County; (49e) sandstone 1 mile (1.6 km.) south of Mount Zion Church, and 4 miles (6.4 km.) northeast of York, York County; and (49f)^a sandstones of Mount Holly Gap, South Mountain, Cumberland County; all in Pennsylvania.

(47a) Sandstone on the southwest side of Sallings Mountain, 2 miles (3.2 km.) east of Natural Bridge, Rockbridge County, Virginia.

(47c) Sandstone 2 miles (3.2 km.) west of Harpers Ferry, Jefferson County, West Virginia.

OBOLELLA MOBERGI Walcott.

Plate LV, figures 3, 3a-f.

? *Obolus?* sp. KJERULF, 1873, Om Skuringsmærker, Glacialformationen, Terrasser, og Strandlinier, etc., 2: Sparagmit-fjeldet, p. 83, figs. 10 and 11. (No text reference.)

Obolella mobergi WALCOTT, 1901, Proc. U. S. Nat. Mus., vol. 23, pp. 673-674. (Described and discussed as below as a new species.)

General form ovate, with the ventral valve subacuminate and the dorsal valve obtusely subacuminate; valves moderately convex; beak of the ventral valve slightly elevated above the plane of the shell; beak of the dorsal valve curved down to the plane of the margin. Surface of the shell marked by concentric lines and striæ of growth, and in some examples by rather strong, radiating, broken, and slightly irregular raised lines of the same character as those of *Bicia gemma* (Billings). The shell is formed of a thin outer layer, and numerous inner layers or lamellæ over the anterior half of the shell. These imbricating inner lamellæ are oblique to the outer layer, very much as in *Obolella (Glyptias) favosa* (Linnarsson).

A ventral valve 10 mm. in length has a width of 9 mm. A dorsal valve 9 mm. long has the same width.

The area of the ventral valve is of medium length and tipped back from the edge of the valve to meet the beak; it extends well out onto the cardinal slopes, and is divided midway by a narrow furrow. The surface of the area is marked by rather strong transverse striæ crossing the area. On each side of the base of the pedicle tube there is a rather strong undercut which in the cast is replaced by a marked toothlike projection. The area of the dorsal valve is narrow. The cast of the pedicle tube or foramen is large, cylindroconical, and encircled by a number of rather strong lines of growth (Pl. LV, fig. 3c).

The casts of the interior of the ventral valve show a central visceral area, very much like that in *O. crassa* (Hall); also two strongly marked vascular sinuses that extend well into the

^a Doubtfully identified from this locality.

middle of the valve. No clearly defined muscle scars are shown on any of the specimens. Casts of the interior of the dorsal valve give little satisfactory data in relation to the muscle scars. The cast illustrated by Plate LV, figure 3e, shows a part of the outline of the visceral area, also the impression of the transmedian muscle scar.

Observations.—This species has been considered as the European representative of *O. crassa* (Hall), which occurs at the same relative stratigraphic horizon at Troy, New York. The Swedish form differs specifically from the American in having a slightly more elongate pedicle tube and in having the interior thickenings of the area more strongly developed. It differs from *O. atlantica* Walcott and *O. chromatica* Billings in having a much more robust shell and in many slight details.

Kjerulf [1873, p. 83, figs. 10 and 11] illustrates, without text reference, a form that appears to be referable to this species. It is found in Locality 324, at Tomten, Norway, in association with *Holmia kjerulfi*, *Arionellus*, and *Obolella (Glyptias) favosa*.

The specific name was given in honor of Dr. J. C. Moberg.

FORMATION AND LOCALITY.—Lower Cambrian: (321v) Gray sandstone of the *Mesonacis torelli* zone at Bjorkelunda, south of Simrishamn, Province of Christianstad; and (321s) brown sandstone interbedded in gray sandstone at Sularp, near Lund, Province of Malmöhus; both in Sweden.

(8v) Shales and dark, calcareous, ferruginous rock in the upper portion of the *Holmia kjerulfi* zone, Ringsaker; and (324 [Kjerulf, 1873, pp. 73 and 83]) green shales with interbedded calcareous sandstone at Tomten, in Ringsaker; both in the Province of Hedemarken, Norway.

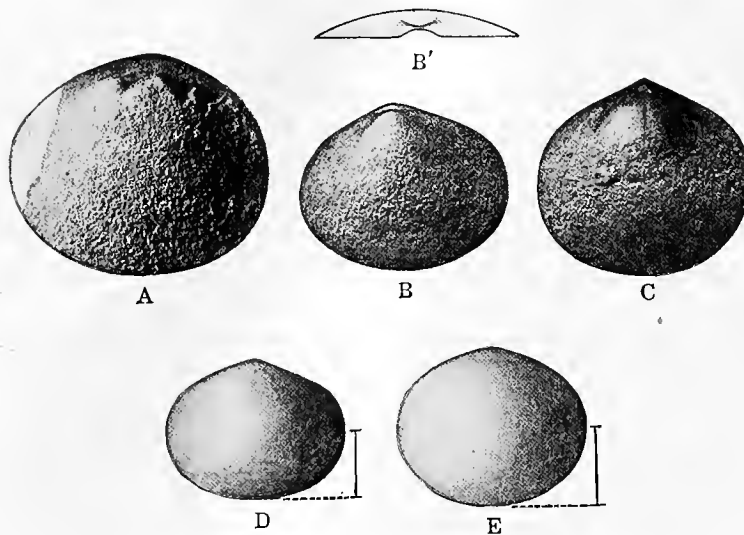

FIGURE 53.—*Obolella vermilionensis* n. sp. A, Cast of the interior of a ventral valve, the type specimen ($\times 2$), from Locality 60b, Lower Cambrian sandstones in Vermilion Pass, Alberta, Canada (U. S. Nat. Mus. Cat. No. 56606a). B, B', Top and back views of a dorsal valve associated with the specimen represented in figure 53A ($\times 2$) (U. S. Nat. Mus. Cat. No. 56606b). C, Ventral valve preserving its shape but from which all traces of shell substance have been removed ($\times 2$). It is associated with the specimens represented by figures 53A and 53B (U. S. Nat. Mus. Cat. No. 56606c). D, Ventral valve from Locality 14p, Lower Cambrian sandstones near Resting Springs, California (U. S. Nat. Mus. Cat. No. 51964a). E, Associated dorsal valve, Locality 14p (U. S. Nat. Mus. Cat. No. 51964b).

OBOLELLA VERMILIONENSIS n. sp.

Text figures 53A-E.

This species is represented by numerous casts in a fine-grained sandstone. General form

suborbicular, slightly transverse. Shells fairly convex and uniformly larger than those of the other species of the genus.

The beak of the ventral valve is somewhat lower than the greatest elevation of the shell, and does not reach the posterior margin. Both the beak and the area are, as a rule, poorly preserved, but the incurving of the growth lines to form the area is well shown in several specimens. Interior casts of the ventral valve show traces of vascular sinuses.

The beak of the dorsal valve terminates at the posterior margin, but is raised slightly above the plane of the margin of the shell.

Shell substance not preserved, but the casts show indications of both radial and concentric striation.

Observations.—The representatives of this species occur in such widely separated parts of the Rocky Mountain province as California and British Columbia, but the forms are identical and are associated in each district with *Holmia* and *Orthotheca*.

Obolella crassa approaches this species in the size of some of its specimens, but it is uniformly smaller and less convex. *Obolella vermilionensis* also differs from the former species in its transverse outline. Further comparison is impossible because of the lack of knowledge as to the interior of *Obolella vermilionensis*.

FORMATION AND LOCALITY.—**Lower Cambrian:** (60b) About 2,300 feet (702 m.) below the Mount Whyte formation and 200 to 300 feet (61 to 92 m.) above the Lake Louise shale, in the St. Piran sandstone [Walcott, 1908a, p. 4], at Vermilion Pass, on the Continental Divide between British Columbia and Alberta, west-southwest of Castle, on the Canadian Pacific Railway, Alberta, Canada.

(53) Sandstones in the lower portion of 3d of the Waucoba Springs section [Walcott, 1908f, pp. 187 and 188], 1 mile (1.6 km.) east of the Saline Valley road about 2.5 miles (4 km.) east-northeast of Waucoba Springs; (312a) sandstones of 3b of the Waucoba Springs section [Walcott, 1908f, p. 187], east of the Saline Valley road east of Waucoba Springs; (14p) sandstone near Resting (Freshwater) Springs, which is in the southwest corner of T. 21 N., R. 8 E., on Amargosa River; (8b) limestone in Tollgate Canyon, about 15 miles (24.2 km.) east of White Pine, White Mountain Range; and (176) shales and interbedded limestones, between massive limestones carrying *Archæocyathus*, at the south end of Deep Spring Valley; all in Inyo County, California.

OBOLELLA WIRRIALPENSIS Etheridge.

Plate LV, figures 7, 7a-b.

Obolella wirriarpensis ETHERIDGE, 1905, Trans. Roy. Soc. South Australia, vol. 29, p. 248, Pl. XXV, figs. 2 and 3. (Described and discussed as a new species. The specimen represented by fig. 2 is redrawn in this monograph, Pl. LV, fig. 7b.)

Obolella wirriarpensis calceoloides ETHERIDGE, 1905, idem, p. 249, Pl. XXV, figs. 4-6. (Characterized and discussed as a new variety. The name placed at the head of the paragraph is "*Obolella* sp.," the term *calceoloides* being applied to it in the text.)

The original description by Etheridge follows:

Valve (? pedicle) ovate to subquadrate, gently convex, rising dorsally into a small umbo; rounded ventrally and without emargination; lateral angles rounded. Internal muscle scars hardly at all curved, diverging from one another, extending far forward, and tapering to a fine point. Surface characters very marked and distinctive, consisting of a series of clean-cut, flat, concentric steps, the "tread" of each step practically at right angles to its "riser;" no concentric or radial striæ of any kind.

After a study of the type specimens of this species and several specimens that were worked out of a block of the limestone received from Mr. Walter Howchin, of the University of Adelaide, I have concluded that the variety *calceoloides* is a narrow form of the species. There are a number of intermediate forms which render it difficult to separate a distinct variety. The species resembles *Obolella crassa* (Hall) in outline and convexity more than any other species referred to the genus.

The specific name is derived from Wirriarpa, the type locality.

FORMATION AND LOCALITY.—**Lower? Cambrian:** (315d [Etheridge, 1905, p. 248]) Limestone near Wirriarpa, Flinders Range, South Australia.

OBOLELLA ? sp. undt.

Obolella cf. *atlantica* DELGADO, 1904, Comunicações Comissão Serviço Geol. Portugal, tome 5, fasc. 2, p. 364, Pl. IV, fig. 35. (Described in French.)

This form, Delgado states [1904, p. 364], is represented by a single specimen, which he compares with *Obolella atlantica* Walcott. The material is too poor to base a specific determination upon. The photograph of the cast of the interior of a small ventral valve 4.5 mm. long and 6 mm. wide indicates that the specimen may be referred to this genus, but it may belong to *Trematobolus*, *Botsfordia*, or an allied genus.

The *Obolella maculata* referred to by Delgado [1904, p. 364] has in this monograph been referred to *Acrothele villaboimensis*.

FORMATION AND LOCALITY.—**Lower Cambrian:** (351 [Delgado, 1904, p. 364]) Shales at Monte de Valbom, to the northeast of Villa Boim, Province of Alemtejo, Portugal.

GLYPTIAS Walcott,^a subgenus of OBOLELLA.

Obolella (*Glyptias*) WALCOTT, 1901, Proc. U. S. Nat. Mus., vol. 23, p. 675. (Mentioned as below as a new subgenus.)

Obolella (*Glyptias*) WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 4, Pl. XI, and pp. 142 and 145. (Classification of subgenus.)

The subgenus *Glyptias* is based on the peculiar surface sculpture and the very short area. Type.—*Lingula* (?) *favosa* Linnarsson.

^a Prior to the definition of this subgenus the type species was described under *Lingula* ? Linnarsson [1869a, p. 356; 1869b, p. 406].

OBOLELLA (GLYPTIAS) FAVOSA (Linnarsson).

Plate LV, figures 2, 2a-d.

Lingula (?) *favosa* LINNARSSON, 1869, Öfversigt af K. svensk. Vet.-Akad. Förhandl. for 1863, vol. 26, No. 3, pp. 356-357. (Described and discussed in Swedish as a new species.)

Lingula (?) *favosa* LINNARSSON, 1869, Geol. Mag., vol. 6, p. 406. (Translation of the preceding reference.)

? *Discina*? sp. KJERULF, 1873, Om Skuringsmærker, Glacialformationen, Terrasser, og Strandlinier, etc., 2: Sparagmit-fjeldet, p. 83, figs. 12 and 13. (No text reference.)

Obolella (*Glyptias*) *favosa* (Linnarsson), WALCOTT, 1901, Proc. U. S. Nat. Mus., vol. 23, pp. 675-676. (Described and discussed essentially as below.)

General form ovate, with the ventral valve subacuminate and the dorsal valve obtusely rounded; valves moderately convex. The dorsal valve is abruptly curved downward at the beak to the plane of the edge of the shell, while the beak of the ventral valve is slightly above the margin, the posterior edges of the shell curving up to meet it. Surface of the shell marked by very fine concentric lines or striæ of growth, crossed transversely by undulating, slightly lamellose lines in almost identically the same manner as in *Obolus* (*Westonia*) *stoneanus* (Whitfield) of the Upper Cambrian of Wisconsin (Pl. XXVIII, fig. 2d). When the outer surface of the shell is exfoliated or worn off by attrition, which is the usual condition, the surface of the inner layers shows fine radiating and concentric striæ. The shell is formed of a very thin, highly ornamented outer layer and numerous inner layers or lamellæ; the latter over the anterior portions are oblique to the outer layer, and when the shell is partly exfoliated they appear as imbricating layers very much as in *Obolus matinalis* (Hall).

The largest ventral valve in the collection has a length of 7 mm. and a width of 6 mm. An associated dorsal valve 6 mm. long has a width of 6.25 mm.

The area of the ventral valve is narrow and rises slightly to meet the beak, which is elevated above the posterior margin. The pedicle tube or foramen is short and small, and, judging from the appearance of the specimens where the beak of the valve is broken away, it opened near the apex of the beak. On the dorsal valve there is no evidence of a true area except in the presence of a narrow, thickened rim somewhat like that of the dorsal valve of *Bicia gemma* (Billings). None of the muscle scars are shown in the ventral valve. The position of the central and anterior lateral scars of the dorsal valve is indicated near the outline of the visceral cavity (Pl. LV, fig. 2c). Of the vascular markings, the main sinuses are clearly shown in each valve, also the outline of the parietal scar. All that is known of them is well shown on Plate LV.

Observations.—This beautiful little shell has remained without illustration since Linnarsson [1869a, p. 356] gave it a name, based on the "singular sculpture" of the outer shell. In a collection made for me by Mr. Schmalensee, a collector in the Geological Survey of Sweden, there were several specimens showing casts of the interior more or less imperfectly. From these I was able to ascertain that the shell has the generic characters of *Obolella*, although differing from the typical species of that genus in the character of the surface ornamentation. The outer surface has been seen only on the posterior umbonal portion of the valves in the shells collected.

Kjerulf [1873, p. 83, figs. 12 and 13] illustrates, without text reference, a form that appears to be referable to this species. It occurs in Locality 324 at Tomten, Norway, in association with *Obolella mobergi*, *Holmia kjerulfi*, and *Arionellus*.

FORMATION AND LOCALITY.—Lower Cambrian: (309c)^a "Fucoid sandstone" at Billingen, east of Skara; and (309d) "fucoid sandstone" at Lugnås, 8 miles (12.8 km.) south-southeast of Mariestad; both [Linnarsson, 1869a, p. 357] in the Province of Skaraborg, Sweden.

(324 [Kjerulf, 1873, pp. 73 and 83]) Green shales with interbedded calcareous sandstone at Tomten, in Ringsaker, near Lake Mjösen, Province of Hedemarken, Norway.

^a Specimens from this locality are included in the collections of the United States National Museum.

Genus *BOTSFORDIA* Matthew.^a

- Obolus* (*Botsfordia*) MATTHEW, 1891, Trans. Roy. Soc. Canada for 1890, 1st ser., vol. 8, sec. 4, No. 6, p. 148. (Merely uses the term "*Obolus* (*Botsfordia*) *pulcher*" in the text.)
- Obolus* (*Botsfordia*) MATTHEW, 1892, Trans. Roy. Soc. Canada for 1891, 1st ser., vol. 9, sec. 4, No. 5, p. 63. (Merely proposed as a new subgenus.)
- Lingulella* HALL and CLARKE (in part), 1892, Eleventh Ann. Rept. State Geologist New York for 1891, pp. 232-233. (The genus *Lingulella* is described; *Lingulella davisii* being given as the type, but *Botsfordia cælata* is figured as the generic illustration on Pl. III.)
- Lingulella* HALL and CLARKE (in part), 1892, Nat. Hist. New York, Paleontology, vol. 8, pt. 1, pp. 55-59. (The genus *Lingulella* is described and discussed, but figures of *Obolus* (*Westonia*) *ella* accompany the text, and *Botsfordia cælata* is figured as the generic illustration on Pl. II. Species belonging with other genera are also mentioned as belonging to *Lingulella*.)
- Mobergia* REDLICH, 1899, Mem. Geol. Survey India, Paleontologia Indica, new ser., vol. 1, No. 1, Cambrian Fauna of the Eastern Salt Range, pp. 5-6. (The description of this new genus is incorporated with that of the new species "*Mobergia granulata*.")
- Botsfordia* MATTHEW, WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 4, Pl. XI, and pp. 142 and 145. (Classification of genus.)

General form moderately convex, subcircular, with the ventral valve more or less obtusely acuminate and the dorsal valve oval. Ventral valve with the beak (apex) close to the posterior margin, perforated with a minute pedicle opening that is separated from the posterior margin by a very short listrium; posterior margin arched above the plane of the side and front margins of the valves. Dorsal valve with a minute beak at the margin.

Surface with concentric lines and ridges of growth and a more or less regular system of tubercles resting upon concentric, rounded, regular or irregular, separate or inosculating ridges; the tuberculated or granulated surface may cover the entire shell or only a portion of it; the tubercles may be arranged in regular order, as in *Botsfordia pulchra* (Matthew) (Pl. LXII), or irregularly, as in *B. granulata* (Redlich) (Pl. LVII).

The shells are small, rarely exceeding a length of 12 mm. Substance corneous, or phosphate of lime and chitin.

Structure of shell lamellated, the inner lamellæ being more or less oblique to the outer layer.

Interior of ventral valve with a small visceral area not exceeding one-half the length of the valve; the pedicle opening is at the posterior end of the visceral area, where the shell usually has its greatest thickness. Vascular sinuses strong, and well within the body of the valve. Muscle scars arranged essentially as in *Obolus*; the transmedian and anterior lateral are close to the main vascular sinus and well back toward the posterolateral part of the valve. So far as known, the centrals and the middle and outside laterals are grouped on each side of the front of the visceral area.

Interior of dorsal valve much like that of *Acrothele*, except that the transmedian muscle scars are separable from the outside and middle lateral scars in one species, *Botsfordia granulata* (Redlich); otherwise they appear to be grouped within the cardinal muscle scar. Median ridge long and prominent; main vascular sinuses well developed and well within the sides of the valve; visceral area in the adult usually not more than one-half the length of the valve; central and anterior lateral muscle scars near the center of the valve.

Type.—*Obolus pulcher* Matthew.

^a The synonymy for this genus does not give a complete record of the various genera under which the species now included in *Botsfordia* were formerly placed; it gives only those references in which the genus is discussed or described. To complete the record the following mere generic references are listed:

Orbicula Hall [1847, p. 290].
Brachiopode, nouv. gen. [de Verneuil and Bar-
 rande, 1860, p. 536].

Obolus (*Lingulella*) Walcott [1901, p. 688].
Obolus (*Botsfordia*) Matthew [1902c, p. 95].

Matthew [1895a, Pl. III] has given diagrammatic illustrations and elaborate descriptions of a number of "embryonic" characters of *Botsfordia pulchra*. Prof. W. A. Parks, of the University of Toronto, sent me (in July, 1906) all the material in the Matthew collection representing this genus and species, but I was unable to recognize the originals from which Matthew's drawings were made. It does not seem probable that his figures 2a, 2b, and 2c represent a young shell of this genus, as it is represented with a high false area similar to that of some species of *Acrothele*; the same is true of figure 2g. Of the other figures, 1k, 2k, and 2i appear to be the posterior portions of adult shells from which the anterior portions have been broken away.

There are two slabs of rock in the Matthew collection upon which there are a number of distorted and poorly preserved interiors of the valves, some of which may have been used in constructing restorations of the interior characters.

Matthew [1891, p. 148] regarded *Botsfordia* as a subgenus of *Obolus*, as he did not discover that the ventral valve was perforated with a pedicle opening and that the dorsal valve was much like that of *Acrothele*. Redlich [1899, pp. 5-6] proposed the genus *Mobergia* for a generically similar species, therefore his name becomes a synonym of *Botsfordia*. Redlich [1899, p. 6] compares *Mobergia* with *Obolella*, an observation that was based on keen appreciation of the cleft or pedicle groove and the arrangement of the muscle scars in the ventral valve; the dorsal valve he compared with that of *Acrothele*. He said [1899, p. 6]: "The agreement goes so far that we may consider *Obolella crassa* [Walcott, 1886b, p. 114] and *Acrothele granulata* [Linnarsson, 1876, p. 24] as the extreme forms of *Mobergia*." The difference between the ventral valves of *Obolella crassa* (Hall) and *Botsfordia* is that in the latter the pedicle groove and area have disappeared and a narrow listrium takes the place of the area, the pedicle opening passing through the shell, while in *Obolella* the pedicle opening is above a clearly defined area. The dorsal valve of *Botsfordia* is more like that of *Acrothele*. The young shells of *Obolella* may have been provided with a pedicle opening in the young stages of growth, much like that in the adult stages of *Botsfordia*. *Botsfordia* appears to be a primitive form of *Acrotretidæ* to the extent that the false area of the ventral valve is only a thin band between the pedicle opening and the posterior margin, whereas in *Acrotreta* there is a well-developed false area. *Botsfordia* appears to represent the first, or, at least, an early stage between the open pedicle furrow of *Obolus* and the inclosed pedicle tube of *Acrothele* and *Acrotreta*. *Botsfordia* differs from *Acrothele* by the form of its visceral area and position of the main vascular sinuses in the ventral valve, also the position of the pedicle opening.

The cancellated surface of *Botsfordia pulchra* (Matthew) is similar to that of *Micromitra* (*Iphidella*) *pannula* (White) (compare Pl. LXII, figs. 5, 5a-c, with Pl. IV, figs. 1s, 1t). The forms of surface in *B. granulata* (Redlich) and *B. cæolata* (Hall) are often found in species of *Obolus* (*Westonia*) and *Lingulella* (*Lingulepis*) (Pls. XLIV, XLVII). The surface of *Acrothele* (*Redlichella*) *granulata* (Linnarsson) (Pl. LVI) is similar to that of *Botsfordia granulata* (Redlich) (Pl. LVII). In *Schizopholis rugosa* Waagen the false cardinal area is more developed than in *Botsfordia*, and the apex is elevated. *Schizopholis* appears to be a form intermediate between *Botsfordia* and *Acrotreta*. At present the species of *Botsfordia* known to me are *B. pulchra* (Matthew), *B. cæolata* (Hall), *B. granulata* (Redlich), and *B. ? barrandei* Walcott.

BOTSFORDIA ? BARRANDEI Walcott.

Plate LVII, figures 7, 7a-b.

Brachiopode nouv. gen. DE VERNEUIL and BARRANDE, 1860, Bull. Soc. géol. France for 1859-1860, 2d ser., vol. 17, pp. 536-537, Pl. VIII, figs. 5, 5a-e. (Described and discussed in French as a new species. Figs. 5, 5a-b are copied in this monograph, Pl. LVII, figs. 7, 7a-b, respectively.)

Acrothele POMPECKJ (in part), 1896, Jahrb. K.-k. geol. Reichsanstalt for 1895, Bd. 45, Hft. 3, p. 603. (Discussed in German, changing generic reference; see p. 603 for translation.)

Botsfordia ? barrandei WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 3, pp. 77-78. (Discussion in the preceding reference translated and species described and discussed as on p. 603 as a new species.)

Of this species Pompeckj [1896b, p. 603] writes:

From Barrande's description and figure it is not quite easy to interpret this species. I have before me several specimens of a brachiopod from Coulouma, in the Department of Hérault, which Miquel [1893, p. 9] mentioned as "la *Discina*." I regard this south French form as belonging to the genus *Acrothele*, and believe that it is probably identical with the species mentioned by de Verneuil, Barrande, and Barrois as occurring in Spain.

Having before me the specimens which Miquel collected, and which I have named *Acrothele bergeroni* (Pl. LVIII), I do not think they can be considered the same as the form described by de Verneuil and Barrande. (Compare Pl. LVII, figs. 7, 7a-b with Pl. LVIII, figs. 6, 6a-c.)

From Barrande's description and illustration the following note is written: The shell is about as wide as long, suboval, with pointed beaks; valves moderately convex, with the ventral a little more so than the dorsal. There is a small area on each valve, but no trace of a triangular false deltidium. Beak of ventral valve with a minute pedicle opening. Surface with fine, distinct, concentric striæ. Substance of shell calcareous.

A shell 13 mm. in length has the same width, and the thickness of the two valves united is 5 mm.

Barrande thought that a new genus was indicated, but in the absence of interior characters decided not to name the genus or species. The perforate ventral valve and area suggested *Siphonotreta* to him, but the calcareous shell was opposed to it.

I have referred the shell to the genus *Botsfordia* provisionally and named it after Barrande, whose memory all paleontologists take pleasure in recalling.

The reference to *Botsfordia* is made on account of: (a) the subacuminate ventral valve with minute pedicle opening above a false cardinal area unmarked by a false deltidium; (b) the convex ventral and dorsal valve; (c) the tendency of *Botsfordia pulchra* Matthew to have the substance of its rather thick shell replaced by calcareous matter.

I have attempted to secure specimens of this shell, but unsuccessfully. Until further information can be secured the present reference will serve to indicate the probable relationship of the species.

FORMATION AND LOCALITY.—Middle Cambrian: (350 [de Verneuil and Barrande, 1860, p. 538]) Red limestone of the *Paradoxides* zone, near Adrados, north of Sabero and Boñar, Cantabrian Mountains, Province of Leon, north-western Spain.

BOTSFORDIA CÆLATA (Hall).

Plate LIX, figures 1, 1a-q, 3, 3a-b.

Orbicula cælata HALL, 1847, Nat. Hist. New York, Paleontology, vol. 1, p. 290, Pl. LXXIX, figs. 9a-c. (Described and discussed as a new species.)

Lingulella (?) cælata (Hall), MATTHEW, 1895, Trans. New York Acad. Sci. for 1894-95, vol. 14, p. 126. (Specimens from a new locality characterized and discussed.)

Obolus (Lingulella) bicensis WALCOTT, 1901, Proc. U. S. Nat. Mus., vol. 23, p. 688. (Described and discussed as a new species.)

General form elongate ovate and varying from broad oval to oval acuminate. Ventral valve moderately convex with the longitudinal line nearly flat from a short distance in front of

the apex nearly to the front margin in old shells; in young shells it rises with a gentle slope from the front margin to the umbo; the posterior margin, including some distance along the cardinal slopes, rises and arches gently above the plane of the edges of the front and sides of the valve, which brings the apex or beak close to the posterior margin (Pl. LIX, fig. 1b); pedicle opening small and at the point of the apex or beak.

Dorsal valve more broadly ovate in outline than the ventral, moderately convex, and rather strongly arched toward the beak, which is marginal; the arching of the posterior portion of the valve causes it to fit closely into the upward arching posterior margin of the ventral valve; a shallow median sinus of varying strength and width extends from the umbo toward the front margin, where it usually disappears.

Surface highly ornamented by narrow, closely arranged, concentric, elevated, irregular, and often inosculating lines, on which small round pustules are lined in such a manner as to give a beaded effect to the surface. The width of the ridges and size of the pustules vary on shells from the same localities and from different localities. Often the shells have been worn by attrition so as to be almost smooth, the coarser striae and lines of growth alone remaining; in addition some shells have more or less numerous, rounded, depressed, radiating ridges, which may be quite regular (Pl. LIX, fig. 1h) or very irregular and discontinuous (Pl. LIX, fig. 1c); some shells are without traces of the radiating ridges and others have only the faint outlines of them. The inner layers are usually shiny and marked by concentric lines and striae, and numerous fine radiating striae.

Shell substance corneous; shell rather thin when young, increasing to a rather strong shell in large specimens; it is built up of a rather thin outer layer and several inner layers or lamellae. The largest ventral valve has a length of 10 mm., width of 8 mm., toward the anterior margin; as this shell has been broken near the beak and also at the anterior margin, it probably had a length of 12 to 13 mm.

The interior of the ventral valve shows strong main vascular sinuses, which originate near the pedicle opening, and gradually separate as they extend forward into the valve; beyond the center they curve slightly inward and terminate about the anterior fifth of the length of the valve. A small visceral area extends a short distance forward between the main vascular sinuses; it has a narrow depressed space across the front (Pl. LIX, fig. 1g) that indicates the position of the central, outside lateral, and middle lateral scars; the furrow that extends from near the center of the visceral area to the pedicle opening near the posterior margin is clearly indicated on figure 1e; as the pedicle opening was at the extreme end and with only a very narrow listrium between it and the posterior margin, the cast of it, or any trace of it, is very difficult to find; this is rendered doubly so by the thin posterior portion of the shell breaking off both before being embedded in the sediment and when being worked out of the rock. There may have been a narrow area, but it has not been seen, and nothing definite is known of the muscle scars.

The interior of the dorsal valve shows a short narrow area, from which a rather broad, low, median ridge extends forward beyond the center of the valve; a narrow septum is indicated along the posterior portion of the ridge; strong main vascular sinuses originate beside the median ridge at the back and diverge gradually as they extend into the valve; the position of the central and lateral muscle scars appears to have been the same as in *Obolus* (Pl. LIX, fig. 1I), but they have not been clearly distinguished except one central scar (h); the cardinal muscle scars are large and situated outside of the main vascular sinuses about their own length in advance of the area.

Observations.—This species, like *Botsfordia granulata* (Redlich), is characterized by having the pedicle aperture close to the posterior margin; it also has the same *Obolus*-like arrangement of the visceral area, vascular sinuses, and muscle scars in the ventral valve; it differs in outline, surface, and interior markings from *B. granulata*.

When studying the genus *Lingulella* in 1898 I left *Lingulella cœlata* (Hall) out of the list of species of *Lingulella* [Walcott, 1898b, p. 393], as I was satisfied that it did not belong there, but

it was not until the study of *Botsfordia* Matthew was taken up that a satisfactory generic reference was established.

The shell appears to have been easily broken, as it is very difficult to obtain good specimens, especially of the ventral valve. It was 10 years or more after I began collecting it before a ventral valve was found showing the pedicle opening. In 1901 I described a young shell of this species as *Obolus (Lingulella) bicensis* [Walcott, 1901, p. 688]. By comparison with other small shells from the type locality at Troy, New York, I am satisfied that the Bic specimen is a young shell of *B. cælata*.

Botsfordia cælata is widely distributed in the Lower Cambrian rocks of the St. Lawrence River, Lake Champlain, and Hudson River valleys, and it is one of the oldest of the Cambrian brachiopods of the Atlantic province of eastern North America.

At Troy, and in Washington County, New York, it is associated with the trilobites *Elliptcephala asaphoides* Emmons and *Conocoryphe trilineata* (Emmons) of the Lower Cambrian fauna, and in the Georgia, Vermont, section it is 700 feet lower than *Olenellus thompsoni* (Hall).

FORMATION AND LOCALITY.—**Middle Cambrian:** (308e [Matthew, 1895a, p. 126]) Beds of Division Clb1 of Matthew's [1895a, p. 108] *Protolenus* zone, on Hanford Brook, St. John County, New Brunswick.

Lower Cambrian: (2o) Limestone boulders in conglomerate, on shore at east entrance to harbor at Bic; (2r) limestone boulders in a conglomerate in a cut on the Intercolonial Railway, 2 miles (3.2 km.) west of Bic railway station; and (2p) limestone on south side of road a little west of Bic and half a mile (0.8 km.) west of the road leading to the wharf; all in Rimouski County, Quebec, Canada.

(392c) At the Straits of Belleisle, Labrador.

(319j) Sandstone 50 feet (15 m.) above the base of the section west of Parker's quarry and about a mile (1.6 km.) from the shore of Lake Champlain, in the township of Georgia, Franklin County, Vermont.

(29a) Limestone 1 mile (1.6 km.) below the New York Central Railroad depot at Schodack; (2b) limestone just north of Beman Park, in the northeastern part of the city of Troy, Troy quadrangle (U. S. Geol. Survey); (367i [Hall, 1847, p. 290]) shales near Troy; and (27) even-bedded and conglomerate limestones on the ridge in the eastern suburb of Troy, Troy quadrangle (U. S. Geol. Survey); all in Rensselaer County, New York.

(33) Limestone on the roadside near Rock Hill schoolhouse near North Greenwich, about 5 miles (8 km.) north-northeast of Greenwich; (33b) limestone on M. C. Tefft's farm, 1.5 miles (2.4 km.) east-southeast of North Greenwich, about 5 miles (8 km.) north-northeast of Greenwich; (36b) limestone near schoolhouse No. 12, near Greenwich; (39a) limestone 0.25 mile (0.4 km.) north of Easton Station, 3 miles (4.8 km.) south of Greenwich; and (43a) limestone 1 mile (1.6 km.) east-northeast of Salem; all in the Cambridge quadrangle (U. S. Geol. Survey), Washington County, New York.

(34a) Limestone 1 mile (1.6 km.) west of North Hebron, 5 miles (8 km.) south-southwest of Granville; (38) limestone 0.25 mile (0.4 km.) north of John Hulett's farmhouse about 3 miles (4.8 km.) west of South Granville and 4.5 miles (7.2 km.) southwest of Granville; and (38a) limestone 2 miles (3.2 km.) south of North Granville, on the road which turns south from the road running between that village and Truthville, 4 miles (6.4 km.) west-northwest of Granville; all in the Fort Ann quadrangle (U. S. Geol. Survey), Washington County, New York.

(38c) Shale at the slate quarries on the west side of the valley 1 mile (1.6 km.) north of Middle Granville, Mettawee quadrangle (U. S. Geol. Survey); (34) limestone on roadside a little west of the bridge over Poultney River at Low Hampton, about 5 miles (8 km.) east-northeast of Whitehall, Whitehall quadrangle (U. S. Geol. Survey); (35) Limestones 1.5 miles (2.4 km.) north of Bald Mountain and 3.5 miles (5.6 km.) north-northwest of Greenwich, Schuylerville quadrangle (U. S. Geol. Survey); (35a) shaly limestone on the west slope of the summit of Bald Mountain, 3 miles (4.8 km.) north-northwest of Greenwich, Schuylerville quadrangle (U. S. Geol. Survey); (338h) limestone on the summit of Bald Mountain, about 2 miles (3.2 km.) northwest of Greenwich, Schuylerville quadrangle (U. S. Geol. Survey); and (39) limestone south of the Delaware and Hudson railroad track, on the road running south-southwest from Low Hampton, about 5 miles (8 km.) east-northeast of Whitehall, Whitehall quadrangle (U. S. Geol. Survey); all in Washington County, New York.

BOTSFORDIA GRANULATA (Redlich).

Plate LVII, figures 4, 4a-r.

Mobergia granulata REDLICH, 1899, Mem. Geol. Survey India, Paleontologia Indica, new ser., vol. 1, No. 1: The Cambrian fauna of the Eastern Salt Range, pp. 5-6, Pl. I, figs. 11-18. (The description and discussion of this new species is incorporated with that of the new genus "*Mobergia*.")

General form subcircular, with the ventral valve very obtusely acuminate, and the dorsal valve transversely more or less broadly oval. Ventral valve moderately convex with the

longitudinal line nearly flat from the apex to beyond the center of the valve, where it slopes gently to the anterior margin; on some shells the slope to the apex rises more abruptly and there is a gentle slope from the umbo to the front margin; the posterior margin arches gently upward from the plane of the edges of the front and sides of the valve. Apex directed backward and perforated by a minute pedicle opening; it extends a little beyond the posterior margin, and is separated from it by a narrow false area or rim of shell; on some shells an elongate, more or less crescentiform tubercle occurs on each side of the apex, and just back of them at the end of the depression between them the minute pedicle opening occurs, or there may be a thickening of the shell back of the opening which results in a tubercle, as shown in Plate LVII, figure 4d; in other shells there is simply a thickened rim of shell about the front and sides of the apex with the pedicle opening at the posterior section of it (Pl. LVII, fig. 4c). Dorsal valve moderately convex; it slopes rather abruptly from the umbo to the minute marginal beak and gently to the front; a minute tubercle occurs on each side of the beak of perfect specimens (Pl. LVII, fig. 4b).

Surface marked by concentric lines of growth and low, rounded, more or less obscure radiating ridges that occur on the anterolateral portions, or on the central part, or all across in front of the umbo and sides, or only as faint traces; in addition there is a system of fine undulating, irregular, more or less inosculating, concentric ridges, upon which there are minute rounded tubercles or granules that have no extended systematic arrangement; on some shells the granulated surface extends to the front margin and on others more or less of the front portion of the valves is marked only by concentric lines and traces of the undulating ridges; in some places the granules are arranged in diagonal lines that cross each other obliquely, and then the effect is a modified form of the surface of *Botsfordia pulchra* (Matthew).

The following are measurements of the valves:

Dimensions of valves of Botsfordia granulata (Redlich).

| | Length. mm. | Width. mm. |
|--------------|----------------|---------------|
| Ventral..... | 6.5 | 7.5 |
| Ventral..... | 6.5 | 6.5 |
| Dorsal..... | 4 | 5 |
| Dorsal..... | 4.5 | 5 |

The specimens are embedded in a fine shale and are more or less flattened by compression.

The shells are built up of a thin outer layer and several inner layers or lamellæ slightly oblique to the outer surface. The shell substance is corneous or, according to the author, "phosphate of lime and chitine" [Redlich, 1899, p. 6].

The interior of the ventral valve is essentially the same as that of *Botsfordia pulchra* (Matthew) and *B. cœlata* (Hall); strong main vascular sinuses rise beside the median line close to the posterior margin and gradually diverging, extend forward into the body of the valve nearer to the median line than to the outer margins; the visceral area is about three-eighths the length of the valve and it has a narrow median groove that terminates in a club-shaped anterior end (Pl. LVII, fig. 4g) that suggests the heart-shaped cavity of *Obolus* (Pl. VII, figs. 1, 3, and 6). The position of the transmedian and anterior lateral muscle scars is shown close beside the main vascular sinus; the central scars and outside and middle laterals can not be separated but the space they occupy is indicated at c, Plate LVII, figure 4p. The cast of the pedicle passage through the shell is shown in figure 4i.

The interior of the ventral valve is much like that of *Acrothele coriacea* Linnarsson. (Compare Pl. LVII, fig. 4k, with Pl. LVI, fig. 1e.) There is a median ridge with the main vascular sinuses starting out beside it near the posterior margin and gradually separating as they extend forward into the valve about halfway between the margins of the valve and the median ridge; the cardinal muscle scars are small and close to the median ridge, posterior margin, and main vascular sinuses; the central muscle scars occur on the slope of the median ridge a little back of the center of the valve, and the small anterior laterals close to the median line a little in advance; in young shells the transmedian and middle and outside laterals are combined in

one scar (cl, Pl. LVII, fig. 4k), but in a larger shell the transmedian scars are separated back of the middle and outside lateral scars, which can not be distinguished as separate scars.

Observations.—Redlich [1899, p. 5] proposed the genus "*Mobergia*" for this species. This was well done, but Matthew [1891, p. 148] had previously described *Botsfordia*. *Botsfordia granulata* (Redlich) has the same type of interior in both valves as *B. pulchra* (Matthew), and the granulated surface is of the same general type except that it is more completely developed in *B. pulchra*. There is a strong generic relation to *Botsfordia cæolata* (Hall) but the specific differences are very decided.

Doctor Holland, director of the Geological Survey of India, kindly sent me the type specimens of this species, and through the courtesy of Dr. Fritz Noetling, I obtained for the United States National Museum a fine collection of this species from the Salt Range.

FORMATION AND LOCALITY.—Middle Cambrian: (15r)^a Dark argillaceous shales, at Khussak, Salt Range, India.

BOTSFORDIA PULCHRA (Matthew).

Plate LXII, figures 5, 5a-l.

Obolus? pulcher MATTHEW, HALL and CLARKE, 1892, Nat. Hist. New York, Paleontology, vol. 8, pt. 1, p. 81, Pl. IV κ, fig. 22. (Characterized, questioning generic reference.)

Obolus? pulcher MATTHEW, HALL and CLARKE, 1892, idem, p. 183. (Characterized and discussed, copying Matthew's notes, 1890, p. 154, on the stages of growth and development. Calls attention to resemblance of this species, in growth stages, to *Kutorgina*.)

Obolus (Botsfordia) pulchra MATTHEW, 1894, Trans. Roy. Soc. Canada for 1893, 1st ser., vol. 11, sec. 4, No. 8, pp. 90-91, Pl. XVI, figs. 3 and 3b. (Described and discussed.)

Obolus (Botsfordia) pulchra MATTHEW, 1895, Trans. New York Acad. Sci. for 1894-95, vol. 14, pp. 115-121, Pl. III, figs. 1a-i, 1k, 2a-g, 2i, and 2k (the missing figures are lacking in the reference; they have not been referred elsewhere in this monograph). (With the exception of the note on the horizon in the first paragraph, the text is copied from Matthew, 1890, pp. 151-155. Figs. 1a-i, 2a-g, and 2i are copied from Matthew, 1890, Pl. VIII, figs. 1a-i, 2a-g, and 2i, respectively. Figs. 1k and 2k are copied from Matthew, 1894, Pl. XVI, figs. 3b and 3, respectively.)

Obolus (Botsfordia) pulcher MATTHEW, 1902, Trans. Roy. Soc. Canada for 1902, 2d ser., vol. 8, sec. 4, No. 3, p. 95, Pl. I, figs. 7a-b. (Characterized and discussed.)

General outline subcircular; the ventral valve being obtusely acuminate and the dorsal a little wider than long. Ventral valve gently convex, most elevated at or a little in front of the apex; apex close to the posterior margin and pointed backward; there is a minute pedicle aperture at the end of the apex. The posterior margin of the valve is arched upward so as to leave only a narrow rim between the margin and the pedicle aperture. Dorsal valve moderately convex, more arched toward the front in old shells, and in all shells it arches upward at the posterior margin so as to fit closely against the margin of the ventral valve.

Surface marked by concentric lines of growth that form imbricating ridges at irregular intervals. In addition there is a reticulated surface formed by the presence on the rounded concentric ridges of small tubercles that are rounded quadrilateral in outline and that alternate on the adjacent ridges, so that each tubercle falls opposite the space between the two tubercles in front; this results in rows of tubercles that are apparently arranged in oblique rows extending from the posterolateral margin of the shell on each side obliquely forward to the margin of the shell on the opposite side; the depressions between the tubercles unite and serve to increase the appearance of an oblique reticulate, tuberculated surface; the tubercles are low at the back and high in front. The finely cancellated surface is usually on the posterior half of the shell, the tubercles becoming scattered and often entirely absent over

^a Specimens from the type locality were given to the United States National Museum and this number was assigned to them.

the anterior and lateral portion of the valvès. The interior layers and interior surface show numerous fine, radiating striæ, and there are also a few radiating lines on the anterior portion of the adult shells.

The shell is built up of a thin outer layer and numerous inner layers or lamellæ that are oblique to the outer surface; the oblique layers on the front portion and sides of adult shells terminate at the growth lines, so as to give an imbricated appearance to the surface. Shell substance apparently corneous.

A large ventral valve has a length and breadth of 11.5 mm. A dorsal valve 10 mm. long has a width of 12 mm. These proportions vary slightly in different shells.

The interior of the adult ventral valve is much like that of *Botsfordia cœlata* (Hall). It has a short visceral area between distinctly marked main vascular sinuses that originate one on each side of the median line at the posterior margin, and gradually separate as they extend forward into the valve; no distinct muscle scars have been seen in this valve. The interior of the dorsal valve has a long central ridge extending well toward the front of the valve; at about the center it shows a tendency to bifurcate; the main vascular sinuses originate at the median line near the posterior margin and arch rapidly outward on each side and then obliquely forward into the body of the valve; the muscle scars are represented by an elongate cardinal scar on each side near the main vascular sinus, where it curves forward into the valve; also one central muscle scar on each side of the median ridge a little back of the center of the valve.

Under the description of the genus *Botsfordia* I have referred (p. 602) to the description of the interior of this species by Matthew. I have given above all I can observe on the specimens in the Matthew collection now at the University of Toronto, also on the specimens in the collection of the United States National Museum.

Observations.—This species is so clearly distinct from *Botsfordia cœlata* (Hall) and *B. granulata* (Redlich) that comparison is unnecessary. It agrees with both of the latter species in having the perforated apex of the ventral valve separated from the posterior margin by a narrow rim of shell, also in having a short visceral area and strong main vascular sinuses. The dorsal valves are of the same general type.

FORMATION AND LOCALITY.—Middle Cambrian: (2γ) Sandstone about 25 feet (7.6 m.) above the Lower Cambrian, on the southeast side of Catons Island; and (308d [Matthew, 1894, p. 121]) sandstones of Division C1b2-4 of Matthew's section on Catons Island; both in Long Reach, St. John River, Kings County, New Brunswick.

Genus SCHIZOPHOLIS Waagen.

[σχιζω, I divide; and φολις, a scale.]

- Schizopholis* Waagen, HALL and CLARKE, 1892, Nat. Hist. New York, Paleontology, vol. 8, pt. 1, p. 94. (Copies original description and discusses genus.)
- Schizopholis* Waagen, WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 4, Pl. XI, and pp. 142 and 145. (Classification of genus.)

Revised generic description.—Ventral valve slightly conical with eccentric apex perforated on the posterior side by a minute foramen. On the posterior slope beneath the apex there is a slightly flattened false area across which the striæ of growth of the shell appear. The striæ arch upward near the center and form a narrow false deltidium, very much as in the genera *Acrothele* and *Acrotreta*. The pedicle opening occurs at the apex of the false deltidium and penetrates the apex of the shell. Dorsal valve nearly flat, umbo slightly elevated, beak marginal.

Surface of shell marked by fine concentric lines and striæ of growth, and irregular, interrupted, slightly elevated, radiating ridges which give a rugose appearance to the surface. Shell substance calcareocorneous. Shell built up of several layers or lamellæ.

Type.—*Schizopholis rugosa* Waagen.

Observations.—The generic relations of this shell, as far as can now be determined, are with *Acrothele*. With our present information it differs only in its more marked false deltidium.

The interior of a dorsal valve from the same bed of sandstone is tentatively referred to this species (Pl. I, fig. 4c). The area of the valve is narrow and not clearly defined; it appears to be merged into a small projecting platform that extends in front into a strong median ridge; at each side of the ridge the platform-like area overhangs a little so as to form a slight hollow beneath; the median ridge extends nearly to the front margin of the shell, very much as in the dorsal valve of *Acrotreta sagittalis* (Salter) (Pl. LXXI, fig. 3g).

My interpretation of this shell differs somewhat from that of Waagen [1885, p. 752]. This arises from his thinking that the false deltidium was an open fissure. On cleaning away the dirt I find that there is a depressed triangular space and that the lines and striæ of growth cross the false area and the false deltidium; also that the foraminal opening is a simple circular aperture as in *Acrothele*.

SCHIZOPHOLIS RUGOSA Waagen.

Schizopholis rugosa WAAGEN, 1885, Mem. Geol. Survey India, Paleontologia Indica, 13th ser., Salt Range Fossils, vol. 1, pt. 1, pp. 753-754, Pl. LXXXVI, figs. 2-4. (Described and discussed as a new species. The specimens represented by figs. 3 and 4 are redrawn in this monograph, Pl. LXXXI, figs. 1c and 1, 1a-b, respectively.)

Schizopholis rugosa WAAGEN, 1891, idem, vol. 4, pt. 2, Pl. II, figs. 12-14. (No text reference. With the exception of fig. 4c, which is not copied in 1891, figs. 13, 14, and 12 are copied from figs. 2-4, respectively, of the preceding reference.)

Schizopholis rugosa Waagen, HALL and CLARKE, 1892, Eleventh Ann. Rept. State Geologist New York for 1891, p. 248, figs. 259 and 260. (No text reference. Figs. 259 and 260 are copied from Waagen, 1885, Pl. LXXXVI, figs. 4d and 4b, respectively.)

Schizopholis rugosa Waagen, HALL and CLARKE, 1892, Forty-fifth Ann. Rept. New York State Museum for 1891, p. 564, figs. 259 and 260. (Copy of preceding reference.)

Schizopholis rugosa Waagen, HALL and CLARKE, 1892, Nat. Hist. New York, Paleontology, vol. 8, pt. 1, p. 95, figs. 50 and 51. (Mentioned in discussion of genus *Schizopholis*. Figs. 50 and 51 are copied from Waagen, 1885, Pl. LXXXVI, figs. 4d and 4b, respectively.)

General form ovate. Ventral valve slightly convex, greatest elevation at the apex, which is nearly above the posterior margin; apex minute and perforated by a circular opening. The posterior side of the shell beneath the apex is slightly flattened so as to form a false area, divided midway by a false deltidium formed by the arching of the lines and striæ of growth; an angle is formed at the point where the lines and striæ arch upward, which gives form to the slight depression, or the false deltidium. Dorsal valve nearly flat, except near the umbo, which is slightly elevated, apex marginal, minute.

Surface marked by numerous concentric lines and striæ of growth, and irregular, interrupted, slightly elevated, radiating ridges that vary in size and direction on different shells. The shell is thin on the edges, becoming thicker toward the umbonal portions by the addition of thin layers or lamellæ. The type specimen of the ventral valve has a length and width of 6 mm.

Observations.—This species is allied to *Botsfordia cælata* (Hall). It differs in surface characters, general outline, and the presence of a false deltidium and area.

FORMATION AND LOCALITY.—Middle Cambrian: (357c [Waagen, 1885, p. 754]) Lower portion of the "Neobolus beds" of the Khussak group, in purplish-colored, fine-grained, micaceous sandstone, near the fresh-water springs in a gorge above the salt mines at Kiura (Khewra), Salt Range, India.

Genus QUEBECIA Walcott.^a

Quebecia WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 320. (Mentioned as on p. 610 as a new genus.)

Quebecia WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 4, Pl. XI, and pp. 142 and 145. (Classification of genus.)

^a The synonymy for this genus does not give a complete record of the various genera under which the species now included in *Quebecia* were formerly placed; it gives only those references in which the genus is discussed or described. To complete the record the following generic references are listed:

Obolella Billings [1872a, p. 219; 1872c, p. 357].

Obolella Walcott [1886b, p. 118; 1891a, p. 611].

The description of the species includes that of the genus, as there is only one species now known.

Type.—*Obolella circe* Billings.

The generic name is derived from the city of Quebec, near which the type species occurs.

QUEBECIA CIRCE (Billings).

Plate CIV, figures 7, 7a-g.

Obolella circe BILLINGS, 1872, Canadian Naturalist, 2d ser., vol. 6, No. 2, pp. 219-220. (Described and discussed as a new species.)

Obolella circe BILLINGS, 1872, Am. Jour. Sci., 3d ser., vol. 3, pp. 357-358. (Copy of preceding reference.)

Obolella circe Billings, WALCOTT (in part), 1886, Bull. U. S. Geol. Survey No. 30, p. 118, Pl. X, fig. 3a (not fig. 3). (Original description, Billings, 1872a, pp. 219-220, copied. The specimen represented by fig. 3a is redrawn in this monograph, Pl. CIV, fig. 7e. Fig. 3 represents a specimen of *Obolella chromatica*.)

Obolella circe Billings, WALCOTT (in part), 1891, Tenth Ann. Rept. U. S. Geol. Survey, p. 611, Pl. LXXI, fig. 3a (not fig. 3). (Mentioned. Fig. 3a is copied from Walcott, 1886b, Pl. X, fig. 3a. Fig. 3 represents a specimen of *Obolella chromatica*.)

Billingsella circe (Billings), WALCOTT, 1901, Proc. U. S. Nat. Mus., vol. 23, p. 673. (Merely changes generic reference.)

Quebecia circe (Billings), WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 320-321. (Described and discussed essentially as below.)

General form broad ovate, with front and sides uniformly rounded, planoconvex. Surface marked by fine concentric striæ of growth. A ventral valve 3.5 mm. in length has a width of 4.5 mm. A dorsal valve 4.5 mm. in length has the same width; a larger dorsal valve, 11 mm. in length, has a width of 10.5 mm. Shell rather thick, and composed of calcite in its present condition.

The ventral valve has an elevated umbo terminating in a sharp upward-pointing apex that may be perforate; from the umbo the surface, in young shells, slopes so rapidly that the central and outer portions of the shell are nearly flat, but in older shells moderately convex; area short and divided midway by a relatively broad delthyrium that is nearly covered by a convex deltidium; the inner surface is marked by fine, elevated, rather widely separated, radiating striæ and very fine punctæ; the very broad main vascular sinuses arch forward from a point beneath the umbo and inclose a small, slightly elevated visceral area; a strong cardinal tubercle occurs on each side of the pseudo-area (cl, Pl. CIV, figs. 7a and 7b) which was probably the point of attachment of the cardinal muscle, i. e., transmedian and anterior laterals.

Dorsal valve gently convex in young shells, becoming strongly convex in old shells; no traces of an area have been observed—if present it must have been short and very low, as the beak is nearly at the plane of the margins of the shell; casts of the interior show that the valve was thickened beneath the umbo by a ridge that separated what may be called the umbonal cavity from the main cavity of the valve. On the cast of an old shell a rounded, narrow, longitudinal, median ridge divides the umbonal cavity; on each side of the cavity and beyond it there is the strongly marked path of advance of the transmedian muscle scars; in front of the transverse ridge two strong ridges that extend toward the center of the valve occupy the position of the main vascular trunks; in one specimen a narrow groove extends from the central muscle scar along the inside margin of the ridge (Pl. CIV, fig. 7).

The muscle scars now known are the transmedians and centrals; the former are situated close to the margin of the valve, and the space assigned them may also include the posterior laterals; the central scars are well indicated in several specimens, but no trace has been found of the anterolaterals. The cardinal tubercle (cl) includes the space that was occupied by the several points of attachment of the posterior muscle, i. e., transmedian, outside lateral, and middle laterals; the cast of the tubercle is an elongate depression just inside the margin of the shell.

Observations.—By incorrect interpretation, both Mr. Billings [1872a, p. 220] and myself [1886b, p. 118] identified the dorsal valve of the species as the ventral, and I illustrated [1886b, Pl. X, fig. 3] a dorsal valve of *Obolella chromatica* as the dorsal valve of "*O. circe*." When

studying some material representing the species in the collections of the United States National Museum I noticed the edge of a shell that, on working it free from the matrix, proved to be a ventral valve; two dorsal valves occur on the same bit of rock. Subsequently Dr. J. F. Whiteaves sent me a tablet from the collections of the Geological Survey of Canada, on which six specimens were labeled "*Obolella circe*." No. 1 is a cast of the interior of the dorsal valve of *Obolella crassa* (Hall), and No. 2 the exterior of the same species. Nos. 3 and 6 are ventral valves of *Quebecia circe*, and Nos. 4 and 5 dorsal valves.

With the ventral valve identified, it appeared that the shell was not an *Obolella*, but the type of an undescribed genus in which the ventral valve is elevated at the apex, with strong cardinal tubercles for the attachment of the posterior muscle scars, very much as in *Acrotrreta*, and *Quebecia* was proposed. The cardinal tubercles and the presence of what appears to be the base of the cast of a foraminal tube suggest that the ventral valve was perforate. *Obolella*, *Quebecia*, and *Yorkia* are all strong, calcareous, perforate shells of the older Cambrian fauna, and are evidently closely related.

FORMATION AND LOCALITY.—Lower Cambrian: (3191 [Billings, 1872a, p. 220])^a Limestone boulders in conglomerate at Trois Pistoles, on St. Lawrence River, below Quebec, Canada.

(392c [Billings, 1872a, p. 218]) at the Straits of Belleisle, Labrador.

Family SIPHONOTRETIDÆ Kutorga.

Genus YORKIA Walcott.

Yorkia WALCOTT, 1897, Proc. U. S. Nat. Mus., vol. 19, p. 714. (Described and discussed as below as a new genus.)

Yorkia WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 4, Pl. XI, and pp. 142 and 146. (Classification of genus.)

Shell inarticulate, subcircular to suborbicular in outline. Apex of ventral valve perforate, marginal, with a false area and a pseudodeltidium. The cast of the interior of the valve shows a foramen which penetrated obliquely upward and backward through the thick umbonal portion of the shell. Two narrow furrows converge from the side of the pedicle opening toward the longitudinal mesial depression and then diverge toward the anterolateral portions of the shell.

The dorsal valve has a well-defined area and an obscure pseudodeltidium. The interior of this valve has a pair of broad, diverging, shear-shaped furrows passing directly forward from the beak for a short distance and then diverging to the outer margin, but not sufficiently to affect the outward curve of the inner margin.

Shell substance probably calcareous. External surface marked with more or less prominent concentric striæ and lines of growth.

Type.—*Yorkia wanneri* Walcott.

Observations.—The area and pseudodeltidium of the ventral valve resemble the same parts in *Trematobolus insignis* Matthew, but the pedicle opening is quite different, and generally the interior of the dorsal valves also serves to distinguish the forms. To *Discinopsis* Matthew there is a resemblance in the markings of the interior of the dorsal valve. *Discinopsis*, however, is founded upon a small, apparently corneous shell, which, so far as known, has no area or pseudodeltidium, and it is closely related to *Acrothele*. *Yorkia* differs from *Acrothele* in its pronounced area, substance of shell, and place of origin of vascular trunks. I do not know of any other genus of the Siphonotretidæ with which it can be compared.

The generic name is derived from York, Pennsylvania, near which the type species occurs.

YORKIA? MIQUELI n. sp.

Plate LXXXII, figure 4.

This species is represented by specimens of the ventral valve, that are compressed in arenaceous shale, and distorted dorsal valves. The ventral valve is small, 2 to 4 mm. in diameter; subcircular to transversely oval in outline, with the highest point at the apex,

^aSpecimens from this locality are included in the collections of the United States National Museum.

which is truncated by a circular opening; posterior slope unknown. Surface, as preserved in the arenaceous shale, marked by concentric striæ and lines of growth and obscure, very fine, radiating striæ. The substance of the shell appears to be corneous, and to make up several very thin lamellæ that combined make a thin shell.

The generic reference is doubtful, owing to the corneous, shiny character of the shell. This species and *Yorkia? washingtonensis* Walcott may belong to a new genus or a subgenus of *Yorkia*.

The specific name is given in honor of Mr. J. Miquel, of Barroubio, France.

FORMATION AND LOCALITY.—**Passage beds** between Cambrian and Ordovician, or Lower Ordovician: (342a) Barren quartzitic beds, Coulouma, Department of Hérault, France.

YORKIA? ORIENTALIS Walcott.

Plate LXXXII, figures 3, 3a.

Yorkia? orientalis WALCOTT, 1906, Proc. U. S. Nat. Mus., vol. 30, pp. 569-570. (Described and discussed as below as a new species.)

This species is represented by a single small ventral valve, which has the external characteristics of *Yorkia wanneri* Walcott, of the Lower Cambrian. The outline of the valve is transversely and broadly oval in outline exclusive of the apex rising above the posterior margin; the apex gives a subtriangular outline to the valve when looking down upon it; the apex is moderately elevated and projects over the posterior margin; it is perforated by a rather large aperture just above a small false area.

The surface of the valve is marked by low, rather broad, concentric undulations, a few fine, concentric striæ, and a very fine reticulate ornamentation formed by the crossing of oblique, elevated, curved lines, which form slightly elongate diamond-shaped pits between them. Shell substance apparently calcareous. Width of ventral valve, 2.5 mm.; length, 2 mm. at aperture, 2.25 at apex; elevation, 0.5 to 0.75 mm.

Observations.—As far as may be determined by the exterior of the valve, this species is properly referred to *Yorkia*. The generic reference, however, will remain in doubt until information is available as to the characters of the interior of the valve.

FORMATION AND LOCALITY.—**Middle Cambrian**: (C71) Massive cliff-forming limestone in the central portion of Kichou formation [Willis and Blackwelder, 1907, pp. 139 and 145 (2d list of fossils)], 4 miles (6.4 km.) south-southwest of Tungyu, Shansi, China.

YORKIA WANNERI Walcott.

Plate LXXXII, figures 1, 1a-i.

Yorkia wanneri WALCOTT, 1897, Proc. U. S. Nat. Mus., vol. 19, p. 715, Pl. LX, figs. 1, 1a-e. (Described and discussed as below as a new species. The specimens represented by figs. 1, 1a-e are redrawn in this monograph, Pl. LXXXII, figs. 1a, 1c, 1g, 1h, and 1i, respectively; figs. 1b and 1c of the original reference (Pl. LX) being both drawn from the specimen represented in fig. 1g of Pl. LXXXII of this monograph.)

Shell subcircular to suborbicular in outline, moderately convex, with the apices of the valves marginal. Ventral valve highest at the beak, which is truncated by a circular foraminal opening; cardinal slope angular and slightly incurved, so as to form a narrow false area on each side of the slightly convex, rather broad pseudodeltidium. Numerous casts show the pseudodeltidium, false area, and a large filling or cast of the foramen which extended obliquely backward through the thickened umbonal portion of the shell to the apex. On a cast of the interior of the valve there are two elongated muscular or vascular (probably the latter) impressions that extend from the anterolateral base of the foraminal opening inward nearly to the median line, and then diagonally outward toward the anterior lateral margin of the shell. There is also a slight median longitudinal ridge that corresponds to a depression in the interior of the shell (Pl. LXXXII, figs. 1b and 1c). In other casts striæ or lines only are shown

radiating outward from the base of the foramen. Fine transverse striæ cross the narrow area and then incurve and cross the pseudodeltidium.

The dorsal valve has a well-defined area, with an obscure pseudodeltidium parting it midway. The cast of the interior of the valve shows two broad, shear-shaped diverging ridges that extend from near the apex to the center of the shell. Numerous vascular markings extend outward from the ridges. These ridges may indicate the muscular scars or merely the main trunks of the vascular depressions. The surface of the area is marked by fine transverse striæ that abruptly incurve toward the front of the area, so as to follow along its anterior margin to the pseudodeltidium.

The surfaces of both valves, as shown in the casts, are smooth, except where marked by concentric lines of growth.

Shell substance unknown, but probably calcareous. It is dissolved away in all the specimens in the collection, only the impression of the shell remaining in the decomposed arenaceous limestone.

This species occurs in abundance, associated with *Nisusia festinata*, *Hyolithes americanus*, and fragments of *Olenellus*.

The specific name was given in honor of Mr. Atreus Wanner.

FORMATION AND LOCALITY.—**Lower Cambrian:** (49) Sandstone on Codorus Creek 0.125 mile (0.2 km.) below Meyer's mill, near Emigsville; and (49a) sandstone on the Liverpool road, south of the schoolhouse, 3 miles (4.8 km.) northwest of York; both in York County, Pennsylvania.

Specimens that are somewhat doubtfully referred to this species occur at the following localities:

Lower Cambrian: (20) Limestone boulders in conglomerate, on shore at east entrance to harbor at Bic, Rimouski County, Quebec.

(7) Shaly beds about 1,000 feet (305 m.) above the quartzitic beds, Silver Canyon, White Mountain Range, Inyo County, California.

YORKIA? WASHINGTONENSIS Walcott.

Plate LXXXII, figures 2, 2a.

Yorkia? washingtonensis WALCOTT, 1897, Proc. U. S. Nat. Mus., vol. 19, pp. 715-716, Pl. LX, fig. 3. (Described and discussed as below as a new species. The specimen represented by fig. 3 is redrawn in this monograph, Pl. LXXXII, fig. 2.)

Ventral valve longitudinally ovate, depressed, convex. Area and pseudodeltidium invisible, but, from the character of the foramen and its resemblance to the foramen of *Y. wanneri*, it is probable that the area was somewhat similar to the area of that species. The cast of the interior of the ventral valve shows a rather long, large foramen, in advance of which two ridges (vascular trunks) diverge somewhat as in the ventral valve of *Y. wanneri* Walcott (p. 612). There is also present a short longitudinal depression in the cast, which indicates a corresponding mesial ridge just in advance of the foramen. The surface of the interior of the shell is marked by fine concentric lines and very fine interior ridges. Shell substance apparently corneous.

This species is founded upon two partial casts of the ventral valve, preserved in compact gray limestone. The shell appears to be very thin over the outer portions and thick over the umbonal region.

The generic reference is somewhat doubtful. *Obolella* is suggested by the cast of the pedicle tube, also *Trematobolus*. The pedicle tube and form of the vascular trunks suggest *Yorkia*, while the shell substance is more like that of *Botsfordia*.

The specific name is derived from Washington County, New York.

FORMATION AND LOCALITY.—**Lower Cambrian:** (37b) Limestone 0.25 mile (0.4 km.) east of Salem, Cambridge quadrangle (U. S. Geol. Survey), Washington County; (338n) western belt of conglomeratic limestone, Rensselaer County; and (38a) limestone 2 miles (3.2 km.) south of North Granville, on the road which turns south from the road running between that village and Truthville, 4 miles (6.4 km.) west-northwest of Granville, Fort Ann quadrangle (U. S. Geol. Survey), Washington County; all in New York.

Genus DEARBORNIA Walcott.

Dearbornia WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 3, p. 78. (Mentioned as below as a new genus.)
Dearbornia WALCOTT, 1908, idem, vol. 53, No. 4, Pl. XI, and pp. 142 and 146. (Classification of genus.)

This genus is based on one species, which is well represented by fourteen specimens. The generic description is incorporated with the description of the type species.

Type.—*Dearbornia clarki* Walcott.

The generic name is taken from Mount Dearborn, named after Gen. Henry Dearborn, near which the type specimens were collected.

DEARBORNIA CLARKI Walcott.

Plate LXXXII, figures 7, 7a-d.

Dearbornia clarki WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 3, pp. 78-80, Pl. VIII, fig. 7. (Described and discussed as below as a new species. Fig. 7 is copied in this monograph, Pl. LXXXII, fig. 7.)

Shell subequivalve, subcircular in outline, slightly convex. Ventral valve most elevated at the pedicle aperture, which is circular, rather large, and situated from one-fifth to one-sixth the length of the valve from the posterior margin; the slope back of the foramen is gently rounded and without a trace of false area or pedicle groove; the position of the beak is not clearly defined, as the margin is rounded and the uniform slope of the outer surface is unbroken. Dorsal valve uniformly and slightly convex; the position of the beak is indicated by a slight projection of the outline of the valve.

Surface marked by fine concentric lines. The substance of the shell is calcareous in an oolitic limestone in which semiphosphatic shells of *Obolus* are preserved. The shell is thick and apparently formed of one layer, but this is probably, as in the case of the shells of *Obolella crassa* (Hall), a condition of preservation, the original layers or lamellæ having been replaced or else cemented together. The average size of the valves is from 3 to 5 mm.

The interior of the ventral valve does not show a true area; there is a space between the margin and the end of the median furrow, into which the foramen opens. The median furrow is rather broad and deepest at the foramen; it extends forward beyond the center of the valve; the furrow into which the foramen opens is broadest at the posterior end, and runs out to a point a little in advance of the opening; from each side of the furrow and opposite the opening a furrow extends obliquely outward and then forward subparallel to the median furrow. Two large, oval muscle scars occur in the space between the outer furrow and the posterolateral margin of the shell; these scars correspond in position to the transmedian and anterior lateral muscle scars of *Obolus* and *Trematobolus*. Nothing is clearly shown of the position of the main vascular canals unless the grooves outside of the median depression indicate their position, or it may be that they were on the narrow ridges outside of the side furrows and inside of the lateral muscle scars.

The interior of the dorsal valve shows a rudimentary area much like that of *Rustella edsoni* Walcott (Pl. I, fig. 1c); the area is a smooth space, with a slightly defined central depression from which a narrow, low median septum extends forward to about the center of the valve; a narrow ridge extends forward from the posterior central depression on each side at about the inner third of the distance between the median septum and the outer margin; these ridges probably marked the position of the main vascular sinuses. The central muscle scars (h) occur in the shallow depression on each side of the median septum, a little back of the transverse center of the valve, and the transmedian scars and outside laterals are just outside of the narrow ridges on each side of the valve; these scars, like those in the ventral valve, are large for so small a shell.

Observations.—*Dearbornia clarki* is one of the simple or rudimentary forms of Siphonotretidae. It differs from *Siphonotreta* in the absence of an area and a siphonal or pedicle tube, in having the pedicle opening on the umbo in advance of the beak, and in its calcareous shell. The circular pedicle aperture without an exterior furrow, the absence of a well-defined area on the ventral valve, and its calcareous shell distinguish it from *Trematobolus* and *Schizambon*. The form and position of the pedicle opening suggest *Discinopsis*, but the interiors of the valves

are very dissimilar in the two genera. It may be that with the discovery of good exteriors of the ventral valve of *Trematobolus excelsis* Walcott that species will be found to have a circular pedicle opening of the same character as that of *Dearbornia clarki*, but from the similarity of the cast of the interior of the ventral valve of the former species to that of *Trematobolus kempnum* (Matthew) it is referred to *Trematobolus*.

The specific name is given in recognition of Dr. William B. Clark's work on the paleontology of Maryland.

FORMATION AND LOCALITY.—**Middle Cambrian:** (9k) Limestone forming 1c of the Dearborn River section [Walcott, 1908f, p. 201], on North Fork of Dearborn River, in the eastern part of the Lewis and Clark National Forest, Lewis and Clark County, Montana.

Genus TREMATOBOLUS Matthew.^a

[τρημα, perforation; and Obolus.]

Trematobolus MATTHEW, 1893, Canadian Rec. Sci., vol. 5, pp. 276-279. (The species *Trematobolus insignis* is described and discussed, the description of the new genus and notes on its position being incorporated.)

Trematobolus MATTHEW, HALL and CLARKE, 1892,^b Eleventh Ann. Rept. State Geologist New York for 1891, p. 252. (Described.)

Trematobolus MATTHEW, HALL and CLARKE, 1892,^b Forty-fifth Ann. Rept. New York State Museum for 1891, p. 568. (Copy of preceding reference.)

Trematobolus MATTHEW, 1894, Trans. Roy. Soc. Canada for 1893, 1st ser., vol. 11, sec. 4, No. 8, pp. 88-90. (Except for the last paragraph, this is a copy of Matthew, 1893a, pp. 276-279.)

Trematobolus MATTHEW, 1895, Trans. New York Acad. Sci. for 1894-95, vol. 14, pp. 122-125. (A copy of the preceding reference.)

Protosiphon MATTHEW, 1897, Geol. Mag., new ser., dec. 4, vol. 4, pp. 68-69. (Described and discussed as a new genus.)

Protosiphon MATTHEW, 1898, Trans. Roy. Soc. Canada for 1898, 2d ser., vol. 4, sec. 4, No. 2, pp. 129-130. (Described and discussed.)

Trematobolus MATTHEW, WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 4, Pl. XI, and pp. 142 and 146. (Classification of genus.)

Shell rather thick, subcircular or oval in outline, biconvex; valves inarticulate. Ventral valve with the beak at or very near the posterior margin. Pedicle opening in front of the beak, at the anterior end of an elongate external groove that begins at the beak and broadens out to the foramen, which is a simple opening through the thick shell; the elongate depression and the opening through the shell are marked by strong lines of shell growth. Dorsal valve usually more convex than the ventral; beak marginal.

Shell built up of several layers or lamellæ that appear to be calcareoconeous, as the result of the replacement in part of the original shell. Cardinal area of the ventral valve short; it rises from the plane of the margins of the valves at angles varying from 25° to 85°; it varies in width and outline with the configuration of the valve. Area of dorsal valve nearly on the plane of the margins of the valves or rising at angles as high as 15°. The area of the ventral valve is divided midway by a distinct furrow that varies greatly in width and depth; in some specimens it is little more than a faintly impressed line (Pl. LXXXIII, fig. 1g) and in others it is an elongate triangular furrow (Pl. LXXXIII, fig. 1i); in some specimens the inner angle of the area next to the median furrow projects forward so as to form a toothlike knob, which, in the cast, is shown by a deep, sharp indentation on each side of the cast of the median furrow. These knobs are the teeth described by Matthew [1893a, p. 277]. They correspond to similar projections in *Obolella* (Pl. LV, figs. 1e, 1f, 3c), and *Bicia gemma* (Pl. L, figs. 1i-k). The area of the dorsal valve is narrow and divided by a central, slightly depressed triangular space; the areas of both valves are crossed by strong, sharp, transverse striæ of growth that pass uninterruptedly across the median furrow.

There are no traces of the foraminal groove on the interior of the ventral valve; it is entirely within the substance of the shell and did not form a ridge on the inside of the shell. A cast of the groove is shown in Plate LXXXIII, figure 1o.

The splanchnocœle of the ventral valve is back of the center, while in the dorsal valve it extends to the center; a median depression extends nearly to the front of the splanchnocœle of the ventral valve into which the foramen opens at about the posterior two-fifths of the

^a The synonymy for this genus includes only those references in which the genus is discussed or described. To complete the record *Obolus* Matthew [1893a, p. 121; 1902c, p. 96] should be listed.

^b This date (1892) is taken from the title-page and is used throughout this monograph, but the work is clearly antedated, the correct date being 1893 or 1894.

length of the depression; traces of a median septum occur in the dorsal valve. The grooves of the main vascular canals begin in each valve at the front margin of the area and arch outward and forward, and then, after passing the center of the valve, curve gently inward, terminating toward the front of the valve; only traces of the secondary radial canals have been observed. The course of the parietal scar in each valve is probably much like that of *Obolus*. The muscle scars, as far as known, are essentially the same as those of *Obolus*. In the ventral valve the transmedian (i) and anterior laterals (j) occur just outside of the line of the main vascular canals. The position of the outside (l) and middle (k) laterals and central (h) scars is within the areas (c) on each side of the anterior termination of the median depression. In the dorsal valve the centrals (h) and anterior laterals (j) are clearly defined, and the position of the transmedian (i) and outside laterals (l) is indicated. The umbonal scars are small and are situated in the ventral valve close to the sides of the anterior end of the furrow in the area; they have not been recognized in the dorsal valve. Pedicle muscle scars unknown.

Type.—*Trematobolus insignis* Matthew.

Observations.—The above description is quite unlike that given of this genus by Matthew [1893a, p. 276]. It is drawn up from specimens of *Trematobolus insignis*, lent to me, first by Dr. Matthew, and later by Prof. W. A. Parks of the University of Toronto, and a fine series of specimens collected by Mr. S. Ward Loper for the United States National Museum at the type locality. I find that the specimen illustrated and described by Matthew [1893a, p. 276, fig. 1a] as the interior of the ventral valve is a natural cast of the *exterior* of a ventral valve, preserving the cast of the area and the elongate depression formed by the advance of the pedicle opening, and that his dorsal valve (1b) is the cast of the interior of a ventral valve. The type specimen of Matthew's ventral valve [1893a, p. 276, fig. 1a] is illustrated by Plate LXXXIV, figure 5b, and the cast of it by figure 5c. The muscle scars illustrated by Matthew are slight irregularities that existed on the outer surface of the shell, along the stronger lines of growth. The type specimen of Matthew's dorsal valve [1893a, p. 276, fig. 1b] is illustrated by Plate LXXXIV, figure 5; it should be compared with the casts of the interior of the ventral valve of *Trematobolus kempnum* (Matthew) as shown by Plate LXXXIII, figures 1c and 1d.

The generic relations of *Trematobolus insignis* Matthew and *T. kempnum*, the type of the genus *Protosiphon* Matthew [1897a, p. 68], may be seen by comparing Plate LXXXIII, figure 1, with Plate LXXXIV, figure 5c, and Plate LXXXIV, figures 5 and 5a, with Plate LXXXIII, figures 1d and 1j. They appear to be generically the same. The specimens of *Trematobolus insignis* Matthew and *Protosiphon pristinus* (see *Trematobolus pristinus* (Matthew)) came from the same stratum of rock and the same locality, and, with the correct understanding of the valves of the type specimens of *T. insignis*, they may be closely compared, as is done under the description of *T. insignis*.

Trematobolus is closely related to *Schizambon*. The ventral valve in both genera has an oval pedicle opening in front of the beak at the anterior end of an external groove, tapering toward the beak; it is the progressive track of the pedicle aperture, and strong, arched lines indicate its successive positions in different stages of growth. (See Pl. LXXXIII, fig. 1o, which is a cast of the groove and opening in a thick shell.)

In *Siphonotreta* the pedicle opening is in front of the beak, but it does not advance with the growth of the shell as in *Schizambon* and *Trematobolus*. The surface of *Schizambon* is spinose while that of *Trematobolus* is nearly smooth. The shells of the latter are thick and the former relatively thin. The muscle scars, as far as known, are essentially the same in the two genera.

It is interesting to note that, with the exception of the pedicle groove and opening, *Trematobolus* and *Obolella* are closely related.

The species now referred to the genus *Trematobolus* are: *T. insignis* Matthew, *T. pristinus* (Matthew), *T. kempnum* (Matthew), and *T. excelsis* Walcott.

T. excelsis occurs in the Lower Cambrian of eastern central California. It is one of the oldest of the Cambrian brachiopods. The three species from New Brunswick are from near the base of the Middle Cambrian.

TREMATOBOLUS EXCELSIS Walcott.

Plate LXXXII, figures 8, 8a-b.

Trematobolus excelsis WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 3, pp. 80-81, Pl. VIII, fig. 8. (Described and discussed as below as a new species. Fig. 8 is copied in this monograph, Pl. LXXXII, fig. 8.)

Shell transversely oval in outline, with both valves obtusely acuminate. Ventral valve strongly convex, with the minute beak at the posterior margin above a low area; the slope from the highest point of the valve, a little back of the center, is greatest toward the beak and nearly uniform to the front and sides of the valve. Pedicle opening unknown, as no exterior or cast of the exterior of the valve occurs in the material collected; two casts of the interior show the cast of the foramen at about the same position as in *T. insignis* Matthew and other species of the genus. Dorsal valve slightly more transverse than the ventral and about two-thirds as convex; a very slight median flattening occurs at the anterior margin that extends back on the valve, nearly to the beak in some specimens; otherwise the convexity is distributed as in the ventral valve.

Surface marked by a few concentric lines of growth. The shell is rather thin, except over the umbonal and posterior portions of the ventral valve, where it is moderately thick. Its substance is now calcareous, and appears like that of *T. insignis*; the original shell may have been calcareoconeous. A ventral valve 18 mm. in length has the same width; a large dorsal valve 22 mm. long has a width of 27 mm.

The area of the ventral valve is short and divided midway by a depressed subtriangular false pedicle furrow; the presence of pits on each side of the anterolateral margins of the false pedicle furrow indicates that the area at these places projected in the same manner as that of *T. insignis* Matthew and *T. kempunum* (Matthew). (Compare Pl. LXXXII, fig. 8, with Pl. LXXXIII, fig. 1c, and with Pl. LXXXIV, fig. 5.) The cast of the interior of the ventral valve shows a median ridge with the cast of the pedicle opening at about the posterior sixth of the length of the valve; only the imperfect outlines of the splanchnocœle are known; the main vascular sinuses are outlined for a short distance back of the transverse center sufficiently to indicate that their position was about the same as in *T. kempunum*. The position of the anterior lateral (j) muscle scar is clearly shown just outside of the main vascular sinuses; it is elongate oval in outline and a little in advance of the transmedian scar (i); the umbonal muscle scars are close to the median furrow, as in *T. kempunum*.

Interior of dorsal valve unknown.

Observations.—This fine species differs from all other known species of the genus in having the ventral valve more convex than the dorsal and in its greater size. It is the oldest species of the genus, occurring as it does well down in the section of the Lower Cambrian strata, in association with *Olenellus*. There are a large number of specimens of the exterior of the dorsal valve, but only two interior casts of the ventral valve. The dorsal valve of *T. pristinus* (Matthew) and *T. kempunum* (Matthew) also greatly outnumbers the ventral valve in the collections. This circumstance may be owing to the presence of the foraminal furrow and interior median furrows; these would cause the shell of the ventral valve to break more readily than that of the dorsal.

FORMATION AND LOCALITY.—Lower Cambrian: (53) Sandstones in the lower portion of 3d of the Waucoba Springs section; (312) sandstones of 3d of the Waucoba Springs section; and (312a) shales of 3b of the Waucoba Springs section; all east of the Saline Valley road, east of Waucoba Springs [see Walcott, 1908f, p. 187, for position in section], Inyo County, California.

(176 and 178a) Shales and interbedded limestones between massive limestones containing *Archæocyathus* at the south end of Deep Spring Valley; and (176a) sandstone on ridge east of the head of Mazouka Canyon, Inyo Range; both in Inyo County, California.

TREMATOBOLUS INSIGNIS Matthew.

Plate LXXXIV, figures 5, 5a-c.

Trematobolus insignis MATTHEW, 1893, Canadian Rec. Sci., vol. 5, pp. 276-279, figs. 1a-d, p. 276. (Described and discussed as a new species. The specimens represented by figs. 1a and 1b are redrawn in this monograph, Pl. LXXXIV, figs. 5b and 5, respectively. Figs. 5c and 5a of this monograph are drawn from casts of the typical specimens, Matthew, 1893a, figs. 1a and 1b, respectively.)

- Trematobolus insignis* Matthew, HALL and CLARKE, 1892,^a Eleventh Ann. Rept. State Geologist New York for 1891, p. 252, fig. 263. (No text reference. Figs. 263 (1a-d) are copied from Matthew, 1893a, figs. 1a-d, respectively, p. 276.)
- Trematobolus insignis* Matthew, HALL and CLARKE, 1892,^a Forty-fifth Ann. Rept. New York State Museum for 1891, p. 568, fig. 263. (Copy of preceding reference.)
- Trematobolus insignis* MATTHEW, 1894, Trans. Roy. Soc. Canada for 1893, 1st ser., vol. 11, sec. 4, No. 8, pp. 88-90, Pl. XVI, figs. 4a-d. (Except for the last paragraph, this is a copy of Matthew, 1893a, pp. 276-279. Figs. 4a-d are copied from Matthew, 1893a, figs. 1a-d, respectively, p. 276.)
- Trematobolus insignis* MATTHEW, 1895, Trans. New York Acad. Sci. for 1894-95, vol. 14, pp. 122-125, Pl. IV, figs. 2a-d. (Text and figures copied from preceding reference.)
- Trematobolus insignis* MATTHEW, 1895, Bull. Nat. Hist. Soc. New Brunswick, vol. 3, No. 13, p. 95, figs. 1a-d. (No text reference. Figs. 1a-d are copied from Matthew, 1895a, Pl. IV, figs. 2a-d, respectively.)
- Trematobolus insignis* MATTHEW, 1898, Bull. Nat. Hist. Soc. New Brunswick, vol. 4, pt. 1, No. 16, p. 35, figs. 1a-d. (No text reference. Figs. 1a-d are copied from Matthew, 1895a, Pl. IV, figs. 2a-d, respectively.)

Shell subcircular in outline, biconvex, valves inarticulate. Ventral valve gently convex, with the minute beak at the posterior margin, and above a low area. Pedicle opening a rather large, simple, oval opening at the anterior end of a furrow that gradually narrows toward the beak, where it terminates; from the lines of growth in the furrow indicating progressive stages of the advance of the foramen it is evident that the foramen began at or just in advance of the beak, and advanced with the growth of the shell in the same manner as the foramen of *Schizambon* (Pl. LXXXIV, fig. 1); the length of the foraminal furrow varies from one-third to two-fifths of the length of the valve.

The substance of the original shell appears to have been entirely removed by solution and replaced by the limestone. The closely related species *T. kempanum* (Matthew) has a calcareo-corneous shell. That the shell was strong is indicated by the depth of the vascular markings and muscle scars. The outer surface is marked by a few concentric lines of growth. The type specimen is 9 mm. in diameter.

The area of the valve is short and divided midway by a depressed, narrow, subtriangular space, bounded by narrow, slightly elevated ridges that originate just beneath the beak and diverge a little toward the margin of the area, where they unite with the margin and extend forward so as to form two short projections, one on each side of the pseudopedicle furrow on the area; the area slopes forward from the beak at an angle of about 15°; it is marked by rather strong transverse lines of growth.

There are no traces of the posterior portion of the foraminal furrow on the interior of the valve; it is entirely within the substance of the shell. The splanchnocœle extends to about the center of the valve; in front of the area a low, broad swelling begins that extends forward beyond the foraminal opening, where it divides so as to leave a short depressed space, and within, a narrow median ridge; on each side and in front of the line of the pedicle opening there are the obscure outlines of the spaces occupied by the scars of the points of attachment of the central, middle lateral, and outside lateral muscles, very much as in *Obolus* (Pl. VII); these muscle-bearing spaces are finely shown in *T. kempanum* (Matthew) and *T. pristinus* (Matthew) (Pl. LXXXIII, figs. 1d, 1j, 2c). The sinuses of the main vascular canals are broad and strong; they start near the front margin of the area near the median line and extend outward and forward subparallel to the outer margin of the valve to about the transverse median line, beyond which, owing to the broken specimen, they have not been traced. The umbonal muscle scars occur on each side of the median line just beneath the projections of the area beside the false pedicle furrow; they are small and located on a low ridge. The transmedian and anterior lateral muscle scars are elongate oval in outline, close to the outer margin of the main vascular sinus, and placed on a rounded, low ridge; the transmedian scar extends a little outside of the anterior lateral scar at its anterior end; as already stated, the central scars and the middle and outside lateral scars probably occurred in the spaces on each side of the anterior end of the low median ridge.

^a This date (1892) is taken from the title-page and is used throughout this monograph, but the work is clearly antedated, the correct date being 1893 or 1894.

The opening of the foramen in the interior of the valve is on the low median ridge at a point three-fifths of the distance from the area to the anterior end of the median line of the splanchnocœle (visceral area).

Dorsal valve unknown.

Observations.—This species is known only by the type specimens of Matthew. These include a matrix of the ventral valve, represented by Plate LXXXIV, figure 5b, a cast of the interior of a broken ventral valve, figure 5, a fragment of the exterior of a ventral valve showing the foraminal furrow, and a fragment of the cast of the outer surface. As stated under the description of the genus, Matthew [1893a, p. 276] mistook the matrix of the ventral valve for the interior of a ventral valve, and the cast of the interior of a ventral valve for a dorsal valve. The true relations of the specimens are readily seen by comparing them with the specimens of closely allied species on Plate LXXXIII.^a

The type material was collected from a layer of rock that is identical with, or is nearly at the same horizon as, a layer at the same locality carrying numerous specimens of *Trematobolus pristinus* (= *Protosiphon pristinus* Matthew). I would consider the latter a synonym were it not for the position and size of the vascular sinuses in the ventral valve, which are located well out toward the outer margin (compare Pl. LXXXIV, fig. 5, with Pl. LXXXIII, fig. 2c), while in *T. pristinus* they are much nearer the median line of the valve. The interior of the ventral valve of *T. insignis* is more like that of *T. kempnum* (Matthew). (Compare Pl. LXXXIV, fig. 5, with Pl. LXXXIII, figs. 1c, 1i.) Until a larger series of specimens representing *T. insignis* is collected the diagnosis of the genus must depend largely upon the material representing *T. kempnum*.

FORMATION AND LOCALITY.—Middle Cambrian: (301 [Matthew, 1895a, p. 123]) Sandstones of Division 1b2 of Matthew, on Hanford Brook, St. John County, New Brunswick, Canada.

TREMATOBOLUS KEMPNUM (Matthew).

Plate LXXXIII, figures 1, 1a-o.

Protosiphon kempnum MATTHEW, 1897, Geol. Mag., new ser., dec. 4, vol. 4, pp. 70-71, figs. 1-4, p. 70. (Described and discussed as a new species.)

Protosiphon kempnum MATTHEW, 1898, Trans. Roy. Soc. Canada for 1898, 2d ser., vol. 4, sec. 4, No. 2, p. 131, Pl. I, figs. 1a-f. (Text is almost an exact copy of the preceding reference. Figs. 1a-d are copied from figs. 2, 1, 3, and 4, respectively, of the preceding reference.)

General form subcircular to rounded ovate, biconvex, with the dorsal valve about one-third more convex than the ventral; outline of ventral valve obtusely acuminate and dorsal valve broadly rounded posteriorly. Beak of ventral valve marginal above a well-defined area; just in front of the beak a narrow furrow starts that marks the path of advance of the pedicle opening; this furrow is usually from one-fourth to one-third the length of the shell and gradually widens and deepens up to the oval pedicle opening; strong lines of growth, with the curvature of the posterior side of the opening, mark the stages of growth and advance of the opening; these are beautifully shown by the cast of the furrow and opening illustrated by Plate LXXXIII, figure 1o. The furrow and pedicle opening are entirely in the layers of the shell and do not cause a projection on the interior of the valve; the opening is compressed in some specimens, but it is usually of good size, as is shown by a cast of it that extended from the outer to the inner surface; this is represented by figure 1e. The opening is of the same character as that of *Schizambon*, except that it is through a thick shell.

Dorsal valve proportionally a little shorter than the ventral; beak marginal.

Surface marked by a few concentric lines of growth; the inner surface appears to have been smooth. The specimens are preserved in a fine-grained sandstone, and usually in the form of casts; a few show portions of the shell, and these indicate that it was of a calcareo-corneous nature and built up of several rather strong layers or lamellæ. This is also indicated by the cast of the pedicle furrow and opening (fig. 1o).

^a I sincerely regret being obliged to differ so greatly with my friend Doctor Matthew on the interpretation of the types of this species and of the genus *Trematobolus*.

The largest ventral valve in the collection has a length of 14 mm. and a width of 13.5 mm. A dorsal valve 13 mm. long has the same width.

The area of the ventral valve slopes backward and rises from the plane of the margins of the valve at an angle of about 45°. It is divided midway by a false pedicle area that varies in width; it is subtriangular in outline, slightly depressed, and has a narrow median furrow of varying depth that is marked by strong lines of growth; on each side of the inner end of this furrow the area is extended forward as a toothlike projection, very much as in *Bicia* (Pl. L) and *Obolella* (Pl. LV). The area is marked by transverse lines of growth subparallel to its anterior margin. The cast of the area (Pl. LXXXIII, figs. 1c, 1d, 1g, 1i, and 1k) shows the pits made by the projections of the area next to the false pedicle furrow; it was these pits in the cast of the ventral valve of *T. insignis* (Pl. LXXXIV, fig. 5) that Matthew [1893a, p. 276] mistook for the dental sockets of the dorsal valve.

The splanchnocœle of the ventral valve is large and clearly shown; the low, broad, rounded median ridge is about one-half the length of the valve; it broadens out near the pedicle opening and again toward the front; it is marked by a narrow median depression back of the pedicle opening, and, in front of the pedicle opening, by a central, elongate swell surrounded by a narrow furrow. The pedicle opening is clearly defined on nearly all casts of the valve; it is situated about two-fifths the distance from the area to the front end of the ridge on which it occurs. On each side, a short distance back of the front end, an area is outlined that extends obliquely backward to the main vascular sinus; this area may be depressed below the general surface or raised above it; it corresponds to the area in the ventral valve of *Obolus*, in which the central muscle scars and the middle and outside lateral scars occur. (Compare Pl. LXXXIII, figs. 1c, 1d, with Pl. VII, figs. 5 and 13; also with Pl. XIV, figs. 1a and 4a.) The transmedian and anterior lateral muscle scars occur on a rounded ridge just outside of the main vascular sinuses (Pl. LXXXIII, fig. 1d). The umbonal muscle scars are oval in outline and situated close to the posterior end of the central median ridge, and between the ridge and the transmedian muscle scars. The impressions made by the main vascular canals are broad, strong, and continued to the anterior third of the valve; they originate beside the median ridge close to the area, and curve outward and then inward beyond the center of the valve.

The area of the dorsal valve is narrow and divided by a central, slightly depressed, triangular space; it is marked by transverse lines of growth and appears to be on the same plane as the margins of the valves. The splanchnocœle of the dorsal valve extends forward beyond the center of the valve; it is divided by a narrow, median septum, and has an oval depression in it a little back of the anterior lateral muscle scars; the central muscle scars are large, oval in outline, and situated on the outer slope of the rounded ridge about the central depression; the anterior lateral scars are small and placed on the rounded ridge in front of the central depression and close to the median septum. A low, rounded ridge extends obliquely forward into the valve from each side of the median septum; these probably mark the position of vascular canals extending forward from the visceral area; they are shown in Plate LXXXIII, figures 1l and 1n. The transmedian and anterior lateral muscle scars are located close to the outer edge of the main vascular sinus, well back on the posterolateral part of the valve. The main vascular sinuses start back of the visceral area near the median septum and curve outward and then forward about halfway between the central muscle scars and the margin at the center of the valve, and then a little inward before terminating near the front margin.

Observations.—This fine shell was the type of Matthew's genus *Protosiphon* [1897a, p. 68]. I find it to be congeneric with *Trematobolus insignis* Matthew, and rather closely related to that species. This may be seen by comparing Plate LXXXIII, figures 1c, 1d, with Plate LXXXIV, figure 5. The pedicle furrow and aperture is much like that of *Schizambon typicalis* Walcott (Pl. LXXXIV, figs. 1, 1a) except that it is in a thick shell, while that of the latter species is in a relatively thin shell. In 1898 Mrs. Walcott and I collected a large series of specimens at the typical locality, as I wished to illustrate fully this the oldest of the Siphonotretidæ of the *Schizambon* type. The shell occurs above the *Olenellus* zone, at about the same general horizon as *T. insignis* and *T. pristinus*.

The specific name was given in honor of Prof. J. F. Kemp, of Columbia University, New York City.

FORMATION AND LOCALITY.—Middle Cambrian: (2u) Lowest beds exposed on the south side of Long Island; and (308g) shales of Division 1b3 or 1b4 [Matthew, 1897, p. 71] of Matthew's section on Long Island; both in Kennebecasis Bay [see Matthew, 1898a, pp. 124 and 127], St. John County, New Brunswick, Canada.

TREMATOBOLUS PRISTINUS (Matthew).

Plate LXXXIII, figures 2, 2a-h; Plate LXXXIV, figure 6.

Obolus pristinus MATTHEW, 1895, Trans. New York Acad. Sci. for 1894-95, vol. 14, pp. 121-122, Pl. IV, figs. 1a-d. (Described as a new species. The specimen represented by figure 1c is redrawn in this monograph, Pl. LXXXIII, fig. 2f.)

Obolus pristinus MATTHEW, 1902, Trans. Roy. Soc. Canada, 2d ser., vol. 8, sec. 4, No. 3, p. 96, Pl. I, figs. 8a-d. (Characterized. Figs. 8a-d are copied from figs. 1a-d, respectively, of the preceding reference.)

General form biconvex, subcircular to short ovate. Ventral valve rounded acuminate, sometimes a little broader than long; beak marginal above a low area. Pedicle opening at the anterior end of a furrow that gradually narrows to the beak; the foraminal furrow varies in length from about one-third to two-fifths the length of the valve; it is situated in the thickened part of the shell and does not produce a ridge on the interior of the valve. Dorsal valve proportionally a little shorter than the ventral; beak marginal; area, if present, unknown.

Surface marked by fine concentric striæ and lines of growth that show as the front margins of imbricated lamellæ of the shell; very fine radiating striæ (also a few radiating, slightly elevated lines) occur on some specimens, but whether they belong on the epidermal layer or one of the inner lamellæ is unknown; the inner surface is slightly roughened. The substance of the shell has been replaced by the calcareous matter of the matrix, but from the calcareo-corneous nature of the shell of *T. kempianum* (Matthew) it is probable that the original shell of this species was of the same nature. The shells vary in size from 5 to 13 mm. in length; the average is about 9 mm.

The area of the ventral valve is short; otherwise, nothing is known of it. The splanchnocœle extends nearly to the center of the valve; a low ridge starts near the area, and, gradually widening, passes beyond the pedicle opening into an oval depression forming the anterior portion of the visceral cavity; the ridge back of the pedicle opening is marked by a slightly raised median line; the space on each side, between the median ridge and the main vascular sinuses, has a narrow band across the front that extends from each side of the central depressed area diagonally backward to the main sinuses; these bands correspond in position to the spaces occupied by the central muscle scars and the transmedian and outside lateral scars (compare Pl. LXXXIII, fig. 2b, with Pl. VII, fig. 13, of *Obolus*); the anterior lateral muscle scar is close to the main vascular sinus, nearly opposite the pedicle opening. The main vascular sinuses start near the area on each side of the low median ridge, and, with a gentle outward curve, pass the center, and then, with a slight inward curve, reach nearly to the front margin; they do not extend laterally beyond a vertical line drawn midway between the center and lateral margins of the valve. Fine, irregular, secondary radial canals extend outward from the main canal toward the margins.

The splanchnocœle of the dorsal valve extends beyond the center; a very narrow median septum is shown, or else a broad, low, rounded ridge. The main vascular sinuses start near the median line, close to the posterior margin, and curve forward, subparallel to the lateral margins of the valve, gradually getting farther away from the margins as they pass the transverse center of the valve. The central muscle scars are elongate oval in outline and situated back of the center of the valve; the anterior laterals are small and close to the median line.

Nothing is clearly shown of the details of the area of the dorsal valve; it was probably similar to that of *T. kempianum* (Matthew). (Compare figs. 2f and 2g with figs. 1l and 1m, Pl. LXXXIII.)

Observations.—This species is closely related to *T. insignis* Matthew, reference to which is made under that species; it differs in the position of the main vascular sinuses of the ventral

valve, and in the size of the splanchnocœle. *T. kempnum* is a larger shell with different vascular and other scars in the interior of the ventral valve. Figures 2, 2a-d represent specimens collected by S. Ward Loper for the United States National Museum, and figures 2e-h represent the specimens in Matthew's collection, now at the University of Toronto.

FORMATION AND LOCALITY.—Middle Cambrian: (301 [*Matthew, 1895a, p. 123*]) Sandstones of Division 1b2; (2h) sandstones of Division 1b2; and (2i and 2k) sandstones of Division 1b3; all in Matthew's [1895a, p. 108] *Protolenus* zone, on Hanford Brook, St. John County, New Brunswick, Canada.

Schizambon Walcott, WINCHELL and SCHUCHERT, 1895, Nat. Hist. Minnesota, Geology, vol. 3, pt. 1, Paleontology, p. 360. (Copies the original description, Walcott, 1884b, p. 69, and discusses genus.)
Schizambon WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 4, Pl. XI, and pp. 142 and 146. (Classification of genus.)

This genus is described in Monograph VIII of the United States Geological Survey [Walcott, 1884b, p. 69] and very fully in Hall and Clarke's monograph [1892c, p. 113].

The type species is illustrated in this memoir on Plate LXXXIV. The other species now referred to the genus are *S. ? esthonia* Walcott, *S. manitouensis* Walcott, and *S. priscus* Matthew. As stated in the original description [Walcott, 1884b, p. 69] *Siphonotreta fissa* Kutorga appears to belong to the genus, and Hall and Clarke [1892b, pp. 115-116] include *Schizambon ? canadensis* (Ami);^a Messrs. Winchell and Schuchert [1895, pp. 361 and 362] tentatively include *S. ? dodgei* and *S. ? lockei*, and Mr. George H. Hudson [1904, p. 284] describes a new species, *Schizambon duplicimuratus*, from the Chazy limestone on Valcour Island, Lake Champlain, New York.

Type.—*Schizambon typicalis* Walcott.

SCHIZAMBON ? ESTHONIA n. sp.

Plate LXXXIV, figure 4.

This species is represented by a single specimen of the ventral valve. It is nearly circular in outline and moderately convex. Apex a little in advance of the posterior margin; a slight flattening back of the apex outlines a faint false area. A wedge-shaped depression extends from the sharp apex forward a short distance to its larger end where the large oval foramen occurs; this depression is similar to that in *Schizambon typicalis* Walcott and *S. fissa* (Kutorga); it is marked by fine lines of growth back of the foramen. Surface marked by fine concentric lines of growth and three narrow, low, concentric ridges or varices of growth; the entire surface is finely granulated, the granules being formed apparently by the crossing of fine, curving, oblique furrows that start on the posterolateral margin and curve forward obliquely across the shell, crossing so as to form rhomboidal spaces in which the granules occur. This type of surface is unlike the spinose surface of *S. typicalis*. It suggests the surface of *Micromitra* and some forms of *Obolus* (*Westonia*). From some points of view the crossing of the depressed lines gives a punctate appearance to the surface.

It may be that this shell belongs to some other genus, but with the present information it is referred to *Schizambon*.

The specific name is derived from Esthonia.

FORMATION AND LOCALITY.—Upper Cambrian: (336h) Ungulite grit, at Baltischport, Esthonia, Russia.

^a *Siphonotreta scotica canadensis* Ami, 1887, Ottawa Naturalist, vol. 1, No. 9, p. 124.

SCHIZAMBON MANITOUENSIS n. sp.

Plate LXXXIV, figures 3, 3a-e.

General form and convexity much like those of *Schizambon typicalis* Walcott, also surface characters if the influence of the different matrix is allowed for. The differences between the two species are in the larger foramen in *S. manitouensis*; in a shorter depression before the beak; in the interior markings of the dorsal valve and the strong area of the dorsal valve (Pl. LXXXIV, fig. 3c). There may be a similar area in *S. typicalis*, but owing to the condition of preservation it has not been observed.

The finely spinose surface is rarely seen, as it adheres to the matrix. The usual appearance of the shell is like that shown by figure 3. The average shell has a length of 4.5 mm., width about the same. Substance corneous.

The specific name is derived from Manitou, Colorado.

FORMATION AND LOCALITY.—Lower Ordovician: (186 and 186a)^a Near line of contact between the red and gray Ordovician limestone, in siliceous red limestone about 30 feet (9.1 m.) above the pre-Cambrian rocks, Williams Canyon, Manitou; and (360) red siliceous limestone near Colorado Springs; both in El Paso County, Colorado.

SCHIZAMBON PRISCUS Matthew.

Plate LXXXIV, figures 2, 2a-e.

Schizambon priscus MATTHEW, 1901, Bull. Nat. Hist. Soc. New Brunswick, vol. 4, pt. 4, No. 19, pp. 277-278, Pl. V, figs. 4a-d. (Described and discussed as a new species. None of the specimens figured are reproduced in this monograph.)

Schizambon priscus MATTHEW, 1903, Geol. Survey Canada, Rept. Cambrian Rocks Cape Breton, pp. 187-189, Pl. XI, figs. 6a-d. (Description and figures copied from preceding reference.)

Shell small and subcircular to transversely ovate, moderately convex. Ventral valve slightly acuminate, with the apex above a short false area, and lower than the umbo. Foramen small, oval, and opening externally into an elongate groove tapering toward the beak; back of the foraminal opening a tapering ridge extends to the beak, leaving a narrower groove on each side. In the interior of the shell the edges of the tapering groove are slightly elevated and the foraminal opening appears to be of about the same size as the external opening. On some specimens of the ventral valve, on each side of the foramen on the outer surface, a narrow depression extends forward and slightly outward nearly to the front margin; this character corresponds to the low ridges in the ventral valve of *Schizambon typicalis* Walcott (Pl. LXXXIV, fig. 1a).

The dorsal valve is less convex than the ventral, and its beak is marginal. The interior of the valve shows a median ridge of varying strength, and the same is true of the ridges indicating the narrow main vascular canals. In figure 2c the anterior portion of the median ridge is shown, also the oval, widely separated central muscle scars (h) and the small anterior lateral scars (j); in figure 2d the main vascular canals and the central portion of the median sinuses are shown. In figure 2e there is only a trace of vascular markings.

Surface as preserved, marked by very fine radiating and concentric ridges that form on some shells a cancellated pattern; the fact that many shells adhere by the outer surface to the matrix leads me to suspect that the outer surface is roughened and probably spinose as in other species of the genus. The average size of the shells is about 4 mm. in length and width. Shell substance corneous.

FORMATION AND LOCALITY.—Upper Cambrian: (10f and 10g) Shales on the east branch of Barachois River, 0.75 mile (1.2 km.) north of the crossroad from Boisdale to Upper Leitches Creek; (10h) at same locality as Locality 10f, but in shales of a slightly different horizon; (10e) shales on the east branch of Barachois River, 0.5 mile (0.8 km.) north of the crossroad from Boisdale to Upper Leitches Creek; (101) shale on east bank of Barachois River, 6 miles (9.6 km.) from Little Bras d'Or Lake; (13h) shale on the east bank of Barachois River, 1.5 miles (2.4 km.) north of Boisdale; (10k) shale on west bank of Barachois River, about 0.25 mile (0.4 km.) north of the Boisdale road; (10d) shale on the west side of Barachois River, 0.125 mile (0.2 km.) north of the Boisdale road, opposite McMullin's place; (10i) shale in high bank on the west side of Barachois River, just north of the Boisdale road; (307 [Matthew, 1903, p. 188]) shales of Division C3c of Matthew on McLeod Brook (=Barachois River); (3q) shale in Barachois Glen, 4 miles

^a186a is the type locality.

(6.4 km.) south of Little Bras d'Or Lake; (3h) shale and shaly limestone on McNeil Brook, 1.5 miles (2.4 km.) east of Marion Bridge; and (372e [Matthew, 1903, p. 50]) shales on McMullins Brook, near McLeod Brook (=Barchois River); all in eastern Cape Breton, Nova Scotia, Canada.

(308 [Matthew, 1901a, p. 278]) Shales of Division C3c of Matthew at Navy Island, St. John Harbor, St. John County, New Brunswick, Canada.

Specimens somewhat doubtfully referred to this species occur at the following locality:

Upper Cambrian: (10c) Shales in a horizon 50 feet below that of Locality 10k, on the west side of Barchois River, eastern Cape Breton, Nova Scotia, Canada.

SCHIZAMBON TYPICALIS Walcott.

Plate LXXXIV, figures 1, 1a-d.

Schizambon typicalis WALCOTT, 1884, Mon. U. S. Geol. Survey, vol. 8, pp. 70-71, Pl. I, figs. 3, 3a-d. (Described and discussed as a new species. Figs. 3, 3a-d are copied in this monograph, Pl. LXXXIV, figs. 1a, 1, 1c, 1b, and 1d, respectively.)

Schizambon typicalis Walcott, HALL and CLARKE, 1892, Eleventh Ann. Rept. State Geologist New York for 1891, p. 253, Pl. IV, figs. 18-20. (Mentioned under genus *Schizambon*. Fig. 18 is copied from Walcott, 1884b, Pl. I, fig. 3a.)

Schizambon typicalis Walcott, HALL and CLARKE, 1892, Nat. Hist. New York, Paleontology, vol. 8, pt. 1, pp. 114, 116, and 117; fig. 65, p. 114; and Pl. IV, figs. 27-30. (Mentioned in discussion of genus *Schizambon*. Fig. 65 is copied from Walcott, 1884b, Pl. I, fig. 3a. Figs. 27 and 29 are copied from figs. 19 and 20, respectively, of the preceding reference.)

This species is fully described in Monograph VIII of the United States Geological Survey [Walcott, 1884b, pp. 70-71]. There is little to add to the description. For comparison with the other species the original figures are reproduced.

Among the fossils occurring in limestone boulders from Locality 30w there is a single specimen of a ventral valve of a shell that appears to be identical with *Schizambon typicalis*. The points of identity are: (a) general form; (b) shape of foraminal opening; (c) fine, elevated, concentric striæ. The only difference is the greater convexity, which is owing, I think, to the character of the matrix, the Nevada specimen being in a shaly limestone and somewhat compressed.

FORMATION AND LOCALITY.—**Lower Ordovician:** (201a) *Pogonip limestone*, east slope of the ridge east of Hamburg Ridge, Eureka district [Hague, 1892, Atlas], Eureka County, Nevada.

Upper Cambrian: (30w) Drift boulder of limestone supposed to have come from 1a of the Notch Peak limestone on Notch Peak [Walcott, 1908f, p. 175], found about 2 miles (3.2 km.) south of Marjum Pass, House Range [Walcott, 1908f, Pl. XIII], Millard County; (33d)^a thin-bedded blue limestone at the base of the first high point southwest of the J. J. Thomas ranch, on the east side of the Fish Spring Range, Juab County; and (54c) about 1,100 feet (335.3 m.) above the Middle Cambrian and 120 feet (36.6 m.) below the top of the Upper Cambrian in the central portion of the limestone forming 1 of the St. Charles formation [Walcott, 1908f, p. 192], in Blacksmith Fork Canyon, about 10 miles (16.1 km.) east of Hyrum, Cache County; all in Utah.

Genus SIPHONOTRETA de Verneuil.^b

[σίφων, a siphon or tube; τρητός, perforated.]

Crania EICHWALD (in part) [not RETZIUS], 1829, Zoologia specialis, vol. 1, p. 273. (Described in Latin. The genus includes species other than those belonging with *Siphonotreta*.)

Terebratula EICHWALD (in part) [not LHWYD], 1840, Jour. Natur- und Heilkunde Medizinischen Akad. St. Petersburg, pts. 1 and 2, p. 138 (p. 24 in second part of one edition). (Merely places "*Crania unguiculata* and *C. verrucosa*" in this genus.)

Terebratula EICHWALD, 1842, Die Umwelt Russlands, Hft. 2, p. 145. (Merely mentions "*Terebratula unguiculata*.")

Siphonotreta DE VERNEUIL, 1845, Géologie de la Russie d'Europe, by Murchison, de Verneuil, and de Keyserling, vol. 2, pt. 3, p. 286. (Described in French as a new genus.)

Siphonotreta de Verneuil, KUTORGA (in part), 1848, Verhandl. Russ.-kais. min. Gesell. St. Petersburg for 1847, No. 12, pp. 261-263. (Described and discussed in German. Notes on the genus occur at various places on pp. 250-260.)

Siphonotreta de Verneuil, MORRIS, 1849, Annals and Mag. Nat. Hist., 2d ser., vol. 4, pp. 315-320. (Notes on the genus and its generic relations.)

^a This species is somewhat doubtfully identified from this locality.

^b The synonymy for this genus is not complete; it includes only those references dealing with the species taken up in this monograph.

- Siphonotreta* de Verneuil, WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 4, Pl. XI, and pp. 142 and 146. (Classification of genus.)

For the diagnosis of the genus, see Hall and Clarke [1892c, pp. 110-113].

The following notes are the result of the study of casts of a natural mold of the interior of the two valves united that I worked out from a specimen of *S. unguiculata* (Pl. LXXXI, figs. 6, 6a-b) received from Dr. Fr. Schmidt, in which the transverse diameter is 18 mm.

The cast of the interior of the ventral valve shows that the visceral area was elevated on a thickening of the shell, and that the muscle scars were attached in depressions in front of and beside the elevated visceral area; the main vascular canal was also on a ridge where it passed from the anterolateral edge of the visceral area. The points of attachment of the central, outside lateral, and middle lateral scars are not clearly defined as distinct scars in the specimens at hand, but the space occupied by them is very distinctly marked. It is very much like that of *Obolus apollinis* Eichwald (Pl. VII). The points of attachment of the transmedian and anterior lateral muscles are close to the elevated visceral area, just outside of the ridge beneath the main vascular sinuses. The opening of the pedicle tube is not well preserved; this feature is illustrated by Davidson [1877, Pl. II, figs. 8 and 9].

The interior of the dorsal valve shows a thickening of the shell in front of the anterolateral muscle scars so as to form a transverse ridge that unites with the median ridge and a ridge on each side that appears to have been beneath the main vascular canals; within the subtriangular space thus formed the rather large anterolateral muscle scars occur as pits, and a little back of them, and of about the same size, the elongate oval central muscle scars; outside of the lateral ridge occur three large oval scars that correspond in position to the transmedian, outside lateral, and middle lateral scars of the dorsal valve of *Obolus*.

The specimens studied by Davidson illustrate the interior of the ventral valve somewhat better than those before me, but the interior of the dorsal valve does not appear to have been so good.

Type.—*Crania unguiculata* Eichwald.

SIPHONOTRETA? DUBIA n. sp.

Plate LXXXI, figures 7, 7a-b.

Shell small, subcircular in outline. Ventral valve subconical, with the apex a short distance in front of the posterior margin and directed backward; it is truncated by a small, round

opening that penetrates through the shell, but whether the opening is continued as a tube is unknown; a false area is slightly indicated on the slope between the pedicle aperture and the gently upward-arching posterior margin. Dorsal valve depressed in some examples so as to be slightly concave between the minute beak at the posterior margin and the front; in other examples it is flat and in some slightly convex.

Surface of both valves marked by concentric lines of growth and low ridges from which spine bases extend across to the front edge of the next ridge, very much as in *Siphonotreta unguiculata* (Eichwald) (Pl. LXXX); the spine bases are short and scattered on the posterior parts, numerous and elongated toward the front and lateral margins in the adult shells.

The average diameter of the valves is from 3 to 4 mm. Substance of shell probably calcareoconchous; it is calcareous in the specimens, but this appears to have been the result of replacement of the original shell by impure calcite, which has also replaced the substance of associated trilobite tests.

The generic reference is doubtful, as nothing is known of the interior of either valve. The circular pedicle opening distinguishes the species from *Schizambon typicalis* Walcott, which has a similar spinose surface (Pl. LXXXIV, fig. 1d), and relates it to *Siphonotreta*. I think that with full knowledge of this species it will be found to belong to an undefined genus, as it is not probable that *Siphonotreta* was developed so early in Cambrian time.

This form owes its specific name to the doubtfulness of the generic reference.

FORMATION AND LOCALITY.—**Lower Cambrian:** (1v) Shales of No. 3 of the Silver Peak group, Barrel Spring section [Walcott, 1908f, p. 189], 3 miles (4.8 km.) north of Valcalda Spring and 4 miles (6.4 km.) west-northwest of the Drinkwater mine, Silver Peak quadrangle (U. S. Geol. Survey), Esmeralda County, Nevada.

SIPHONOTRETA UNGUICULATA (Eichwald).

Figs. 22 and 23 are copied from Davidson, 1877, Pl. II, figs. 9 and 11, respectively. Figs. 24-26 are copied from Kutorga, 1848, Pl. VI, figs. 2c, 3b, and 3a, respectively.)
- Siphonotreta unguiculata* (Eichwald), HALL and CLARKE, 1892, Nat. Hist. New York, Paleontology, vol. 8, pt. 1, p. 111, Pl. IV, figs. 22-26. (Mentioned. Figs. 22-26 are copied from those in the preceding reference, which see.)

The characters of this species are included in the generic description given by Messrs. Hall and Clarke [1892c, p. 110]. It differs from *S. verrucosa* (Eichwald) in its broader outline and more finely granulated and spinose surface. Figs. 6, 6a, and 6b are of a specimen received from Dr. Fr. Schmidt; fig. 6c is copied from Davidson [1877, Pl. II, fig. 9].

FORMATION AND LOCALITY. *a*—Ordovician: (336g) Limestone in the vicinity of Zarskoe Selo; (336w) near Pawlowsk; and (336x) in the Archangel quarry on the Volkhof (Volkhof); all near St. Petersburg, Russia.

(336v) *Echinosphærites* limestone at Reval; (337d) "Brandschiefer" at Salla, near Erras, 85 miles (137 km.) east of Reval; and (337e) "Jewesche Schicht" at Altenhof, near Pöddrus, 55 miles (88.6 km.) east of Reval; all in the Government of Esthonia, Russia.

Drift bowlders of *Echinosphærites* limestone at the following localities: (386i) Near Wehlau, 30 miles (48.3 km.) east of Königsberg, East Prussia; (386j) at Belschwitz, East Prussia; (386k) near Wormditt, East Prussia; and (386l) near Marienwerder, West Prussia; all in Germany.

Passage beds between the Upper Cambrian and the Ordovician: (336e) *Orthoceratite* limestone at Pulkowa; (337m) *Orthoceratite* limestone at Popowka; (337k) *Orthoceratite* limestone on the banks of Volkhof (Volkhof) River, near Lake Ladoga; and (336y) glauconitic limestone at Popowka; all near St. Petersburg, Russia.

Orthoceratite limestone ("Vaginatenskalk") at the following localities: (336z) At Narwa; (337) at Erras, 85 miles (137 km.) east of Reval; (337a) at Kusal, 25 miles (40 km.) east of Reval; (337b) *b* at Reval; (337c) on Odensholm Island, 55 miles (88.6 km.) west of Reval; and (337l) at Baltischport, west of Reval; all in the Government of Esthonia, Russia.

SIPHONOTRETA VERRUCOSA (Eichwald).

- Siphonotreta verrucosa* (Eichwald), QUENSTEDT, 1885, Handbuch der Petrefactenkunde, Auflage 3, p. 755, Pl. LVIII, figs. 52 and 54. (Discussed in German.)
- Siphonotreta verrucosa* (Eichwald), GAGEL, 1890, Beitr. zur Naturkunde Preussens, von Physikal.-oekonom. Gesell. Königsberg, 6, p. 22, Pl. I, figs. 2a-b. (Characterized in German.)

This beautiful and instructive species is described by de Verneuil [1845, p. 287]. Figures 5, 5a, and 5b are drawn from a specimen received from Dr. Fr. Schmidt. The outer opening of the pedicle tube is a little longer than wide, and slightly pointed toward the minute beak, which is at its posterior margin. There is no trace of a groove or pseudodeltidium on the false area of this species or *Siphonotreta unguiculata*.

a Localities 336y and 337m are represented in the United States National Museum collections; the other localities are taken from the references in the synonymy. The authority for each reference cited will be found in the list of localities, pp. 161-291.

b May be the type locality. Eichwald [1829, p. 274] gives it as "limestone at Reval."

FORMATION AND LOCALITY.^a—Ordovician: (336w) Near Pawlowsk, near St. Petersburg, Russia.

Drift bowlders of *Echinospharites* limestone at the following localities: (386i) Near Wehlau, 30 miles (48.3 km.) east of Königsberg, East Prussia; (386k) near Wormditt, East Prussia; and (386 l) near Marienwerder, West Prussia; all in Germany.

Passage beds between the Upper Cambrian and the Ordovician: (336e) *Orthoceratite* limestone at Pulkowa; (337m) *Orthoceratite* limestone at Popowka; and (336y) glauconitic limestone at Popowka; all near St. Petersburg, Russia.

(337f) "Vaginatenkalk"^b at Türsel, 15 miles (24.2 km.) west of Narwa; and (337g) "Vaginatenkalk"^b at Chudleigh, 25 miles (40 km.) west of Narwa; both in the Government of Esthonia, Russia.

Genus KEYSERLINGIA Pander.^c

Orbicula DE VERNEUIL (in part) [not LAMARCK], 1845, *Géologie de la Russie d'Europe*, by Murchison, de Verneuil, and de Keyserling, vol. 2, pt. 3, p. 288. (Described and discussed in French. Of the species included in the genus only "*Orbicula buchii*" is treated in this monograph.)

Not *Orbicella* DANA, 1846; see Scudder's *Nomenclator Zoologicus*, p. 236. (Proposed for a genus of the Polypi.)

Orbicella D'ORBIGNY (in part) [not DANA], 1850, *Prodrome de Paléontologie*, vol. 1, p. 20. (Characterized in French. "*Orbicella buchii*" is the only one of the many species placed under the genus which is treated in this monograph.)

Keyserlingia PANDER, 1861, *Bull. Acad. imp. sci. St.-Petersbourg*, tome 3, columns 46-48. (Described and discussed in German.)

Keyserlingia Pander, DALL, 1877, *Bull. U. S. Nat. Mus. No. 8*, p. 39. (Merely listed, but gives "*Orbicula reversa*" as the type.)

Orbicella d'Orbigny, DALL (in part), 1877, *idem*, p. 50. (Cites *Orbicella buchii* as the type and gives synonymy of genus.)

Keyserlingia Pander, OEHLERT, 1887, *Manuel de conchyliologie*, by Fischer, p. 1263. (Described in French, with figures of *Keyserlingia buchii*.)

Not *Keyserlingia* KARPINSKY, 1887, *Bull. Acad. imp. sci. St.-Petersbourg*, tome 31, p. 476, footnote. (The use of the name *Keyserlingia* in this reference is clearly a typographical error, "*Helmersenia*" being the proper term.)

Orbicella d'Orbigny, HALL and CLARKE, 1892, *Eleventh Ann. Rept. State Geologist New York for 1891*, p. 254. (Pander's original description, 1861, p. 46, translated.)

Orbicella d'Orbigny, HALL and CLARKE, 1892, *Forty-fifth Ann. Rept. New York State Museum for 1891*, p. 570. (Copy of preceding reference.)

Keyserlingia Pander, HALL and CLARKE, 1892, *Nat. Hist. New York, Paleontology*, vol. 8, pt. 1, pp. 117-119. (Copies the translation of Pander's original description given by Hall and Clarke, 1892a, p. 254, and discusses the genus and the priority of the generic names proposed for it.)

Keyserlingia Pander, WALCOTT, 1908, *Smithsonian Misc. Coll.*, vol. 53, No. 4, Pl. XI, and pp. 142 and 146. (Classification of genus.)

The description of the type species, *Keyserlingia buchii*, gives all that is known of this genus. My description and remarks are based on the study of a considerable number of specimens collected for me by Mr. Schmalensee at Jaggowal, Esthonia, and a few received from Dr. Fr. Schmidt, collected at Kunitz, Government of Pskow.

From the means of comparison with other related generic forms it appears that *Keyserlingia* has an interior pedicle tube somewhat like that of *Siphonotreta unguiculata* (Eichwald), but that the pedicle cleft is back of the apex as in *Schizotreta elliptica* Kutorga. A young shell has a very clear opening in the pedicle cleft, but in nearly all adult shells the opening is closed. In the interior of the ventral valve of many shells the pedicle tube extends forward into the valve (Pl. LXXXI, fig. 4a), but in adult shells it is often closed by a vesicular growth of shell (fig. 4b).

Keyserlingia, as exemplified by *K. buchii*, is a form having an external pedicle cleft back of the apex much like that of *Schizotreta*, and an interior pedicle tube extending forward a varying distance but not usually beyond the center.

Type.—*Orbicula buchii* de Verneuil.

The generic name was given in honor of A. de Keyserling.

KEYSERLINGIA BUCHI (de Verneuil).

Plate LXXXI, figures 4, 4a-e.

Orbicula buchii DE VERNEUIL, 1845, *Géologie de la Russie d'Europe*, by Murchison, de Verneuil, and de Keyserling, vol. 2, pt. 3, pp. 288-289, Pl. XIX, figs. 1a-c. (Described and discussed in French as a new species.)

^a Localities 336y and 337m are represented in the United States National Museum collections; the other localities are taken from the references in the synonymy. The authority for each of the localities cited will be found in the list of localities, pp. 161-291. I have been unable to determine which is the type locality.

^b The *Vaginoceras* limestone is the equivalent of the *Orthoceratite* limestone.

^c The synonymy for this genus is not complete; it includes only those references dealing with the species taken up in this monograph.

Orbicella buchi D'ORBIGNY (in part), 1850, *Prodrome de Paléontologie*, vol. 1, p. 20. (Changes generic reference, but includes "*Orbicula reversa*" also as a synonym of "*Orbicella buchi*.")

Discina buchii (de Verneuil), EICHWALD (in part), 1860, *Lethæa rossica, ancienne période*, vol. 1, sec. 2, p. 914. (Described and discussed in French. Eichwald includes Jeremejew's *Siphonotreta ladogensis* as a synonym.)

Keyserlingia buchi (de Verneuil), PANDER, 1861, *Bull. Acad. imp. sci. St.-Petersbourg*, tome 3, columns 46-48, Pl. II, figs. 1a-h. (Described and discussed in German.)

Orbicella buchi (de Verneuil), HALL and CLARKE, 1892, *Eleventh Ann. Rept. State Geologist New York for 1891*, p. 254, Pl. IV, figs. 8-10. (Mentioned as the type species. Figs. 8, 9, and 10 are copied from Pander, 1861, Pl. II, figs. 1a, 1h, and 1c, respectively.)

Keyserlingia buchi (de Verneuil), HALL and CLARKE, 1892, *Nat. Hist. New York, Paleontology*, vol. 8, pt. 1, p. 118, Pl. IV, figs. 1-3. (Note fixing "*K. buchi*" as the type species. Figs. 1-3 are copied from Hall and Clarke, 1892a, Pl. IV, figs. 9, 10, and 8, respectively.)

Shell inequivalve, circular, or slightly oval longitudinally or transversely. Ventral valve depressed conical with the apex from just in front of the posterior margin to one-fifth of the length of the valve toward the front margin; a roughly outlined false area is formed by the incurving of the posterior slope from each side beneath the apex, to a narrow cleft that extends downward from the apex a varying distance toward the posterior margin; the narrow cleft is usually closed at the bottom, but in some examples it has a small elongate opening midway and in others a minute rounded opening toward the lower or posterior part. The exterior of the dorsal valve is slightly convex with the apex marginal. Surface marked by fine, concentric striæ and a few stronger lines of growth that pass beneath the apex across the false area except where interrupted by the pedicle cleft; when the latter is closed the striæ do not cross the shell substance at the bottom of the cleft. In addition there are faint traces of fine radiating striæ and on some ventral valves a few obscure, low, radiating ridges.

The area of the ventral valve rises from the plane of the margins of the valve at an angle of about 45°; it is slightly arched inward at the center, and is marked by strong striæ of growth parallel to the outer margin. Within the valve a median ridge of varying strength and length extends forward from the front margin of the area. In fifteen examples it is less than one-half the distance to the front margin, and in only one it extends forward beyond the center. On all unbroken specimens a strong projection extends upward from the median ridge just in advance of the area; it is narrow at the base, widening sideways and backward; it has a large variously shaped anterior opening that narrows toward the base of the projection; the size of the projection and opening depends upon the amount of shelly matter that has been deposited on and in it. The opening is the inner end of the pedicle tube; in some examples it is entirely filled with shelly deposit (Pl. LXXXI, fig. 4b), and in others it is still open; in several examples with an open interior aperture the pedicle cleft is closed at the exterior end. The median ridge, in front of the pedicle tube, has a vesicular interior that gives it a hollow appearance when the top is broken away. In several examples the pedicle muscle scar is clearly preserved, on the projection from the median ridge, just in front of the opening of the pedicle tube. On each side of the median ridge close to the area the cardinal muscle scars are either in a depressed pit or on a more or less elevated projecting growth of shell rising from the bottom of the valve; sometimes the projections extend beyond the plane of the margins of the valve (Pl. LXXXI, fig. 4c), and often the central projection about the pedicle tube extends above the plane of the margin. On some shells the area indicated as the cardinal scar shows the points of attachment of three muscles, probably the umbonal, transmedian, and anterior laterals; the only indication of the points of attachment of the muscles corresponding to the central, outside, and middle laterals of *Obolus* is on the sides and beside the elevated pedicle tube.

The area of the dorsal valve has a broad, triangular, slightly concave space at the center that is bounded by narrow flexure lines; on each outer side of the flexure line the area narrows and slopes upward at an angle of about 30° to 45°; it is marked by distinct lines of growth that cross the central depressed space subparallel to the margin of the area. Within the valve a strong median septum extends from the area to the front part of the valve; this septum when broken shows an interior vesicular structure that gives the appearance of its having been hollow. Well toward the front an oval muscle scar (central) occurs on each side of the septum; the cardinal muscle scars are oval in outline close to the area and surrounded by a more or less thickened

shell growth in old shells. Between the large cardinal scars and the outer margin there is a narrow, elongate, depressed area in which the outside and middle lateral muscles may have been attached.

Shell substance corneous. The shell is built up of numerous thin layers or lamellæ, and the thick growth of the old shells is by irregular accretions. The average size of the shells is 5 to 7 mm. in diameter.

Observations.—This interesting form was evidently in its younger stages a siphonate shell that had its pedicle tube closed by shell growth in the adult stage. I have broken several ventral valves on the line of the pedicle cleft and found that the shell within the cleft has a vesicular structure and that the opening could not be traced through the shell. The filling up of the pedicle tube and the deposition of shelly matter about the interior opening of the tube appear to have been a phase of adult growth and old age. The filling of the tube must have cut off the pedicle and left the shell to drift about very much as in the case of *Leptaena rhomboidalis* and *Rhynchotrema capax* [Hall and Clarke, 1894, p. 184].

This species differs from *Orbicula reversa* de Verneuil [1845, p. 289] in having the apex of the ventral valve much nearer the posterior margin.

FORMATION AND LOCALITY.—Upper Cambrian: (395) *Obolus* sandstone at Joa, near Jegelecht, 12 miles (19.3 km.) east of Reval, Government of Esthonia; (395b) *Obolus* sandstone at Ilgast, Government of Esthonia; (9d) *Obolus* sandstone at Jaggowal, about 20 miles (32.2 km.) east-southeast of Reval, Government of Esthonia; (336n [de Verneuil, 1845, p. 289]) on Ijora (*Ischora*) River, Government of St. Petersburg; (336o) Ungulite grit, Koporje, Government of St. Petersburg; (336a [Eichwald, 1860, p. 914]) *Obolus* sandstone at Podolova (Putalova?) on Ijora (*Ischora*) River, Government of St. Petersburg; and (336p) Ungulite grit, Kunitz, Government of Pskov; all in Russia.

Superfamily ACROTRETACEA Schuchert.

Family ACROTRETIDÆ Schuchert.

Subfamily ACROTHELINÆ Walcott and Schuchert.

Genus ACROTHELE Linnarsson.^a

[ἀκροος, at the top; and θηλή, nipple.]

Acrothele LINNARSSON, 1876, Bihang till K. svensk. Vet.-Akad. Handl., Bd. 3, No. 12, pp. 20–21. (Described and discussed in English as a new genus.)

Acrothele Linnarsson, ZITTEL, 1880, Handbuch der Palæontologie, Bd. 1, Abth. 1, p. 665. (Described in German.)

^a The synonymy for this genus does not give a complete record of the various genera under which the species now included in *Acrothele* were formerly placed; it gives only those references in which the genus is discussed or described. To complete the record the following mere generic references are listed:

- Linnarssonia* GRABAU and SHIMER?, 1907, idem, p. 200. (Described, but the only species referred to the genus (*Linnarssonia pretiosa*) is not figured, and it is impossible to tell whether the authors are discussing the *L. pretiosa* that is now referred to the genus *Acrotreta* (*Acrotreta sagittalis*), or to the genus *Acrothele* (*Acrothele pretiosa*.)
- Acrothele* Linnarsson, WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 4, Pl. XI, and pp. 142 and 146. (Classification of genus.)

General form subcircular to transversely broad oval in outline. Ventral valve moderately convex to subconical; a false area is usually more or less distinctly outlined on the ventral valve between the apex (beak) and the posterior margin; pedicle opening on the posterior slope of the apex (or beneath the beak). The only suggestion of a true cardinal area is in *Acrothele bellula* Walcott (Pl. LVIII, fig. 5c); and this appears to be a broadening and slight flattening of the posterior under edge of the shell. Dorsal valve gently convex, and sometimes nearly flat; beak minute, marginal; area known only in *A. bellula* Walcott (Pl. LVIII, figs. 5f-h), where it is short and divided midway by a small, triangular false deltidium, very much as in *Acrotreta definita* Walcott (Pl. LXIV, fig. 2d.)

Surface marked by concentric lines and striæ of growth which cross the false area of the ventral valve; on some species there are low, rounded, radiating ridges that are usually confined to the ventral valve; in addition, on some species, there is a series of more or less inosculating, irregular, fine ridges with tubercles on them, which gives a highly ornamented surface such as occurs on some forms of *Micromitra* and *Westonia*.

The shells of *Acrothele* rarely exceed 13 mm. in diameter, and the average size of adult shells is from 6 to 8 mm. Substance of shell corneous. The shell is built up of several layers or lamellæ that are usually more or less obliquely inclined to the outer surface, over the central and outer portions.

The interior of the ventral valve has a small visceral area about the pedicle opening and extending a short distance in front of it; in several species an elongate depression occurs on each side and a little in advance of the pedicle opening that corresponds to the tubercle on each side of the apex of the outer surface; frequently the shell is thickened beneath the visceral cavity and a short ridge of varying width and length results; the edge of the pedicle opening may be slightly thickened, which forms a callosity or apical swelling, but not to the same extent as in the ventral valve of *Acrotreta*. Nothing has been seen of an area in front of the visceral area corresponding to the trapezoidal areas of *Obolus*, *Acrotreta*, and *Trematobolus*, in which the central, outside lateral, and middle lateral muscles were attached; in fact, it is only very rarely that the impression of the visceral area is shown. The main vascular sinuses start from just back of the pedicle opening, and curve, one on each side, out and then forward into the body of the valve, usually within a line drawn halfway between the center and the outer margin of the valve; many branches from the main sinus occur in some species. The transmedian and anterior lateral muscle scars appear to be merged in the cardinal muscle scar, situated on the outer posterolateral slope, outside of the main vascular sinuses; on one shell what appear to be the umbonal muscle scars are preserved (Pl. LXI, fig. 1c).

The interior of the dorsal valve has a median ridge of varying length and size, and main vascular sinuses that start near the posterior margin and extend directly outward for a short distance, and then obliquely forward in almost a direct line (Pl. LVI, figs. 1d and 1e; Pl. LX, figs. 1k and 1l). The cardinal muscle scars are usually small and close to the posterolateral

margin (Pl. LX, fig. 1k), but larger scars occur and extend farther forward into the valve (Pl. LXII, fig. 1f; Pl. LVIII, figs. 3c, 3d, and 5b). The central and anterior lateral scars are situated essentially as in *Obolus*; the former on the slopes of the median ridge and the latter at the anterior end of the ridge.

Type.—*Acrothele coriacea* Linnarsson.¹

Observations.—The generic description is drawn up from the material studied in connection with the various species now referred to the genus. One of Linnarsson's species, *Acrothele granulata* [1876, p. 24] I have taken as the type of the subgenus *Redlichella* on account of the differences in the interiors of the valves.

Surface characters.—The surface characters of the various species of *Acrothele* vary nearly as much as those of *Micromitra*. The species may be grouped by the surface features under three headings: (1) Striato-granulose; (2) concentrically ridged, striated, or nearly smooth; (3) pseudopunctate.

The first group, striato-granulose or radulo-granulose, includes, as now known, sixteen species and seven varieties. The surface of the type species of the genus, *Acrothele coriacea* Linnarsson, is representative of this form of surface. It has concentric lines of growth, and a series of concentric, irregular, more or less inosculating, rounded, fine ridges upon which minute nodes or granules occur; these granules, on some species, are more or less regularly arranged on the ridges and appear over nearly the entire surface (Pl. LVI, fig. 1g), while in others they are scattered irregularly (Pl. LXI, fig. 4d). On *Acrothele matthewi* (Hartt) (Pl. LXI) and some other species the younger shells are granulated, while on the older shells the ridges are fairly regular and only an occasional granule occurs on them. On most adult shells with this form of surface the ridges near the margin are more regular and rarely inosculate. This type of surface occurs also on *Acrothele (Redlichella) granulata* (Linnarsson) (Pl. LVI, fig. 2g) and *Botsfordia granulata* (Redlich) (Pl. LVII, fig. 4r) and *Botsfordia cælata* (Hall) (Pl. LIX, figs. 1h and 1o).

The species upon which I have seen the ridges and granules are:

Acrothele bellula Walcott has this type of surface, but the ridges and granules are so minute that they are only to be seen with a very strong lens.

The second group is concentrically ridged, striated, or smooth, as far as known. I think, however, that with better-preserved specimens some of the species now included under it would be found to have the striato-granulose surface.

The species referred to it are:

| | |
|--------------------------------------|------------------------------------------|
| <i>Acrothele bohemia</i> (Barrande). | <i>Acrothele?</i> <i>minuta</i> Walcott. |
| <i>borgholmensis</i> Walcott. | <i>Acrothele nitida</i> (Ford). |
| <i>ceratopygarum</i> (Brögger). | <i>turneri</i> Walcott. |

| <i>maculata</i> (Salter). | |

On the pseudopunctate surface the union of the inosculating ridges is very regular and the hollows or pits between the ridges are arranged in oblique lines that appear to start on the posterolateral margins of the valves and curve obliquely forward to the opposite

side (Pl. LVII, fig. 3b). It is the same type of surface as that of *Botsfordia pulchra* (Matthew) (Pl. LXII, figs. 5, 5a-c) and *Micromitra (Iphidella) pannula* (White) (Pl. IV, figs. 1t and 1s). This form of surface is represented by only one species: *Acrothele bellapunctata* Walcott (Pl. LVII, figs. 3, 3a-b).

The surface of the following species has not been definitely determined owing to the condition of preservation. I think most of them will be found to belong to the group represented by *A. coriacea* Linnarsson (p. 642):

- Acrothele dichotoma* Walcott.
- pr. mæva* (de Verneuil and Barrande).
- rara* Walcott.
- villaboimensis* Delgado.
- sp. undt. a* Walcott.
- sp. undt. Moberg*.

The group of forms described by G. F. Matthew [1903, pp. 98-103] from the "Etcheminian" of Nova Scotia, and *A. prima* (Matthew) [1886, p. 41] from New Brunswick, and *A. prima costata* (Matthew) [1895a, p. 128], are all closely related by their general form, usually strong shells, and surface characters; the latter are variable but the range of variation is usually to be found on any large, old shell, an exception being found in radiating ridges, which vary greatly and to a certain extent depend upon conditions that affected the shell after the animal died, such as maceration and distortion by compression and movement in the embedding sediment. The shells above the horizon of the *Paradoxides* zone, represented by *Acrothele matthewi* (Hart), appear to have been affected also by the same conditions, although the sediment is usually finer and more compact.

Pompeckj [1896b, p. 603] thought that the shell described by de Verneuil and Barrande [1860, pp. 536-537] was probably a species of *Acrothele*, and probably the same as the shell collected by Miquel. My study of Miquel's material shows that a true *Acrothele* is represented: *A. bergeroni* Walcott (Pl. LVIII, figs. 6, 6a-c). The other form is biconvex, calcareous, and not a typical *Acrothele*. I have referred to it provisionally (p. 602) as *Botsfordia? barrandei*.

Comparisons with other genera.—The relations between *Acrothele* and *Acrotreta* were recognized by Linnarsson [1876, p. 20] and by all subsequent authors who have had occasion to discuss the genus. Both genera have (a) a more or less elevated ventral valve with a pedicle opening at the summit of a more or less distinctly defined false area; (b) a moderately convex dorsal valve with somewhat similar interior markings; (c) small visceral areas in the ventral valve; (d) corneous shells built up of thin layers.

Acrothele differs from *Acrotreta* (a) in having a depressed ventral valve; (b) a faintly defined false area in the ventral valve; (c) larger size; (d) greater variety and more highly ornamented surface; (e) apparently more complex vascular markings; and (f) a difference in the position of the main vascular sinuses; for the dorsal valve this is best seen by comparing Plate LX, figures 1k and 1l, *Acrothele subsidua* (White), with Plate LXV, figures 1f and 1g. I have examined many hundred specimens of the interior of dorsal valves of *Acrotreta* without finding any traces of the main vascular sinus, whereas in *Acrothele* they are usually present. In the ventral valve the differences are also marked, as the vascular sinuses are proportionally much larger in *Acrotreta*.

There are exceptions to the marked difference in elevation of the ventral valve, as that of *Acrothele subsidua* (White) (Pl. LX, figs. 1a, 1c, and 1d) is nearly as elevated as that of *Acrotreta sagittalis taconica* (Walcott) (Pl. LXXI, figs. 1, 1a-e).

Acrotreta appears to be a somewhat more highly developed form than *Acrothele*, although a smaller shell.

Geographic distribution.—Species of the *Acrothele coriacea* type occur in Sweden, Denmark, Bohemia, southern France, and Portugal in Europe; in eastern North America, in Nova Scotia and New Brunswick; in western North America in Utah, Nevada, Idaho, and Montana. This indicates the wide distribution of one specific type, and other forms extend the distribution

far to the south in the Appalachian province, *A. bellula* Walcott; and to the north in Pennsylvania, *A. yorkensis* Walcott. The general distribution of species is given in the table (p. 105) and the details of each species under the specific description.

Stratigraphic range.—*Acrothele* is represented by eight species and one variety in the upper portion of the Lower Cambrian in association with *Olenellus* or allied forms of trilobites, but in no instance has it been found low down in the Lower Cambrian. In the Middle Cambrian twenty-one species and six varieties occur, and there the genus attained its widest distribution and greatest development. One species, *A. borgholmensis* Walcott, occurs in strata of the *Ceratopyge* zone, and three species in Lower Ordovician formations. Of the latter, *A. ceratopygarum* is not a typical form of *Acrothele*. (See p. 640.)

ACROTHELE ARTEMIS Walcott.

Text figure 54.

Acrothele artemis WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 3, p. 82, Pl. VIII, fig. 10. (Described and discussed as below as a new species. Fig. 10 is copied in this monograph as fig. 54.)

General form of ventral valve moderately convex; subcircular and somewhat obtusely acuminate in outline; apex near the posterior margin; pedicle opening unknown, but from the occurrence of a small boss on the inside of the shell beneath the apex it was probably of the same character as in closely related species.

FIGURE 54.—*Acrothele artemis* Walcott. A, A', Ventral valve with the apex broken. The specimen is from Locality 5b, Middle Cambrian limestones in Twomile Canyon, south-east of Malade, Oneida County, Idaho. (U. S. Nat. Mus. Cat. No. 51909.) The figure is copied from Walcott, 1908d, Pl. VIII, fig. 10.

Surface marked by concentric lines and small ridges of growth, and an irregular system of fine granules on the concentric ridges; in the lower interspaces there is an irregular distribution of very minute inosculating ridges that, with the tubercles, form a surface independent of the concentric growth lines. The shell is built up of numerous lamellæ beneath the outer surface layer and appears to have been corneous, or composed of phosphate of lime and chitin.

The largest shell has a length and width of 10 mm.; the apex is about 2 mm. from the posterior margin; dorsal valve unknown.

Observations.—This species resembles in form *Acrothele prima costata* (Matthew) (Pl. LXI, figs. 4 and 4a), and both species have a granular surface. The latter species, however, has a thinner shell, and its surface is marked by much larger granules. I know of no other closely related species.

FORMATION AND LOCALITY.—Middle Cambrian: (5b) Dark blue-gray Langston limestone [Walcott, 1908f, p. 198], just above the Cambrian quartzitic sandstones, north side of Twomile Canyon, near its mouth, 2 miles (3.2 km.) south-east of Malade, Oneida County, Idaho.

ACROTHELE AVIA Matthew.

Plate LXI, figures 7, 7a-b; Plate LXII, figures 1, 1a-k.

Acrothele avia MATTHEW, 1899, Bull. Nat. Hist. Soc. New Brunswick, vol. 4, pt. 3, No. 18, pp. 202-203, Pl. 111, figs. 1a-h. (Described as a new species. The specimens represented by figs. 1c and 1f are redrawn in this monograph, Pl. LXI, figs. 7a and 7b, respectively.)

Acrothele avia MATTHEW, 1902, idem, pt. 5, No. 20, pp. 396-398, Pl. XVI, figs. 7a-b; Pl. XVII, figs. 1a-f and 2a-b. (Described and discussed. Pl. XVII, figs. 1a-f, and Pl. XVI, figs. 7a-b, are copied from Matthew, 1899b, Pl. III, figs. 1a-h. The specimens represented by figs. 2a and 2b are redrawn in this monograph, Pl. LXI, fig. 7, and Pl. LXII, fig. 1i, respectively.)

Acrothelc abavia MATTHEW, 1902, idem, pp. 398-400, Pl. XVI, figs. 3a-d and 4a-b. (Described and discussed as a new species.)

Acrothele avia MATTHEW, 1903, Geol. Survey Canada, Rept. Cambrian Rocks Cape Breton, p. 55. (Notes on orientation of valves.)

Acrothele avia MATTHEW, 1903, Geol. Survey Canada, Rept. Cambrian Rocks Cape Breton, pp. 98-99, Pl. V, figs. 1a-f and 2a-b. (Described and discussed essentially as in Matthew, 1902a, pp. 396-398. Figs. 1a-f are copied from Matthew, 1899b, Pl. III, figs. 1a-f; figs. 2a and 2b are copied from Matthew, 1902a, Pl. XVII, figs. 2a and 2b, respectively.)

Acrothele abavia MATTHEW, 1903, idem, pp. 100-101, Pl. IV, figs. 3a-d and 4a-b. (Described and discussed as in Matthew, 1902a, pp. 398-400. Figs. 3a-d and 4a-b are copied from Matthew, 1902a, Pl. XVI, figs. 3a-d and 4a-b, respectively.)

This is a strong shell of the *Acrothele matthewi* (Hartt) type. The adult shells are somewhat thicker, the surface is a little different, being coarser, and the callosity in front of the pedicle opening is longer and larger than in *A. matthewi* or its varieties. Matthew [1902a, p. 396] gives as one of the most marked distinctions of this species the presence on the sides of the dorsal valve of "about a dozen radiating, branching, crenulated ridges that extend to the margin." With all of Matthew's types before me, I find one bit of rock with two ventral valves, one partly overlapping the other; on these the radiating ridges not only occur on the sides, but also over the middle of the shell, and where a bit of the shell is broken off the ridges are clearly impressed on the cast of the interior; this specimen is labeled as one of the original types of the species; a second ventral valve preserving a part of the exterior surface also shows traces of radiating ridges. Another type specimen shows part of the exterior surface and the cast of the interior, but there is no trace of a radiating ridge on the outer surface or cast; seven specimens of the dorsal valve on which the outer layer is exfoliated show no traces of the radiating ridges. I find further that the dorsal valves on which the radiating ridges occur are very thin and hence liable to be flexed by lateral pressure, developing surface ridges on the lines of radiating striæ that occur on the inner layers of nearly all shells of *Acrothele*. On the ventral valve a few radiating ridges occur on one of the specimens (Pl. LXI, fig. 7); another specimen, laterally compressed, shows many such ridges (Pl. LXI, fig. 7a). Other specimens are without exterior traces of ridges, but when the shell is exfoliated, numerous fine, radiating striæ with stronger and deeper striæ at wider intervals are to be seen. I have taken up this matter of the radiating ridges at length, as I do not consider the side ridges on the dorsal valve of *Acrothele avia* sufficient to separate it from other species to which it is closely related.

The surface is formed of fine, irregular, concentric, rounded ridges that frequently inoscillate; these ridges are crenulated by fine depressions which cross them and thus outline tubercles or rounded points of varying height and size, depending upon the depth of the radiating cross depressions; this type of surface gives great variety to different parts of the shell and to different shells. As far as I can determine by the use of a strong lens (three-quarter inch) it is essentially the same type of surface as that occurring on *Acrothele matthewi* (Hartt) and related species, one of which is shown by Plate LXI, figure 4d.

At the apex of one of the specimens of the ventral valve in Matthew's collection there are two minute elongate tubercles with a narrow depression between them, and on the posterior slope there is an oval pedicle opening with the narrow end nearest the apex; a low, narrow ridge, that divides the obscure false area midway, extends from the opening to the posterior margin.

"*Acrothele abavia*" Matthew does not appear to vary specifically from the forms of *Acrothele avia* in which the radiating ridges are absent. The specimens occur in a little coarser sediment, and on this account are not well preserved. Matthew [1902a, p. 399] speaks of a small tubercle in front of the pedicle opening and "the visceral callus that extends half of the length of the shell" of the ventral valve; such a tubercle occurs on the only two specimens of *A. avia* well enough preserved to show the interior of the ventral valve. I do not find the elongate visceral callus on any specimens of the ventral valve in Matthew's collection; some specimens do show a short callosity similar to that in *A. avia*. After a very careful study of all the specimens, also of a large collection from the same locality and strata belonging to the United States National Museum, I am led to think that Matthew mistook the median ridge of some dorsal valve in which the posterior portion was broken away as the visceral callosity of the interior of a ventral valve; this belief is further strengthened by his statement [1902a, p. 399]: "On each side of the callus a groove runs out toward the front margin. Some

examples show a median and two lateral septa in front of the callus.' (See interior of dorsal valve as shown by Pl. LXII, fig. 1g.) In the United States National Museum collection, from Matthew's horizon E3a, I find 13 interiors of the ventral valve with short "callus" and 10 typical exteriors, also 22 dorsal valves. There are also fair specimens from horizons 3d and 3e. The shells of horizon 3a have the oblate form of *Acrothele avia* found at horizons 3d and 3e.

Acrothele avia differs from *Acrothele proles* Matthew in having the apex of the ventral valve a little nearer the posterior margin, but not so near as that of *Acrothele prima* (Matthew).

FORMATION AND LOCALITY.—Middle Cambrian: (13d'') Sandstones 10 feet (3 m.) below Division E2a; (13d and 13d') sandstones opposite the third waterfall in Dugald Brook, between Divisions E2a and E2b; (10p) sandstone just below the waterfall in Division E2b; (131 and 131') sandstones of Division E3a; (344 [Matthew, 1903, p. 81]) sandy shales of Division E3b; (344a [Matthew, 1903, p. 26]) sandy shales of Division E3c; (344b [Matthew, 1903, p. 81]) sandy shales of Division E3d; (13n')^a sandstones of Division E3e; and (13n) sandstones of Division E3f; all in Matthew's [1903, p. 21] Etcheminian, on Dugald Brook, Indian River, eastern Cape Breton, Nova Scotia.

(13m) Sandstones of Division E3f of Matthew's [1903, p. 76] Etcheminian, on Gillis Brook, Indian River; and (10p'') sandstone on the small brook on the hill between the bridge over Indian River and McPhees Brook; both in eastern Cape Breton, Nova Scotia.

ACROTHELE AVIA PUTEIS Matthew.

Acrothele avia-puteis MATTHEW, 1902, Bull. Nat. Hist. Soc. New Brunswick, vol. 4, pt. 5, No. 20, p. 398, Pl. XVI, figs. 5a-b. (Characterized as a new variety.)

Acrothele avia-puteis MATTHEW, 1903, Geol. Survey Canada, Rept. Cambrian Rocks Cape Breton, p. 100, Pl. IV, figs. 5a-b. (Characterization and figures copied from preceding reference.)

This seems to be a variety of *Acrothele avia* Matthew. It differs in the possession of a pair of pits, one of which lies on each side of the space between the foramen and the visceral callus, partly overlapping each. The visceral callus is quite short in this form and has but little prominence. The ridges on the surface of the shell are more regularly concentric than in the type, and more sharply cut; about ten are found in the space of 1 millimeter. The cardinal area is curved forward toward the top, and finely striated. The foramen is about a fifth of the length of the valve from the cardinal line, and the front of the callus about a third. Vascular trunks and branches are visible on the surface of the ventral valve as in *A. avia*. The dorsal valve does not sensibly differ from that of *A. avia*.

The largest valve seen was 8 mm. long and about the same width.

The typical specimens of the ventral valve of *Acrothele avia puteis* are slightly different from those of *Acrothele avia*, but not sufficiently so to show clearly in an illustration. The pits beside the median line, between the pedicle aperture and the visceral callosity, do not appear in the specimens of the species, and indeed the condition of the material is such that probably they could not be distinguished if originally present. The visceral callosity is shorter and much like that of *Acrothele matthewi* (Hartt).

FORMATION AND LOCALITY.—Middle Cambrian: (13m) Sandstones of Division E3f of Matthew's [1903, p. 76] Etcheminian, on Gillis Brook; and (344c [Matthew, 1903, p. 100]) sandy shales of Division E3d of Matthew's Etcheminian, on Gregwa Brook; both in the Indian River valley, eastern Cape Breton, Nova Scotia.

ACROTHELE BELLAPUNCTATA Walcott.

Plate LVII, figures 3, 3a-b.

Acrothele bellapunctata WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 3, pp. 82-83, Pl. VIII, figs. 9 and 9'. (Described and discussed as below as a new species. Figs. 9 and 9' are copied in this monograph, Pl. LVII, figs. 3 and 3b, respectively.)

General form a broad transverse oval with the posterior side slightly flattened and arched upward for a short distance below the apex. Ventral valve convex near the umbo and nearly flat over the anterior portion of the valve; apex near the posterior margin. Foraminal aperture apparently at the apex above a short, not distinctly marked, false area. Ventral valve nearly flat and with the posterior margin curved downward so as to fill the space caused by

^a13n' is the type locality, though the specimens in the United States National Museum collections to which that number is assigned were collected later than the type specimens.

the upward arching of the margin of the ventral valve. Surface of shell beautifully ornamented by elevated sharp oblique lines with deep interspaces that give a strongly punctate appearance to the shell; concentric undulations and ridges of growth also occur in a more or less irregular manner. The inner layers or lamellæ are marked by fine, concentric, and rather strong radiating lines. The shell is built up of numerous thin layers or lamellæ of a corneous appearance.

A slightly compressed ventral valve has a length of 5 mm. with a width of 6.5 mm. A ventral valve is 4 mm. in length with a width of 5 mm.

Observations.—This is one of the most beautifully ornamented species of the genus. Its surface is not unlike that of some varieties of *Micromitra* (*Iphidella*) *pannula* (White). In form it suggests *Acrothele* (*Redlichella*) *granulata* (Linnarsson). Nothing is known of the interior character of the valves.

FORMATION AND LOCALITY.—Lower Cambrian: (8v) Shales in upper portion of *Holmia kjerulfi* zone, Ringsaker, Province of Hedemarken, Norway.

ACROTHELE BELLULA Walcott.

Plate LVIII, figures 5, 5a-h.

Acrothele bellula WALCOTT, 1897, Proc. U. S. Nat. Mus., vol. 19, pp. 716-717, Pl. LX, figs. 4, 4a-e. (Described and discussed as a new species. Figs. 4, 4a-e are reproduced (with slight changes) in this monograph, Pl. LVIII, figs. 5, 5a, 5c, 5f-h, respectively.)

General form transversely broad oval, with the posterior margin slightly transverse. Ventral valve slightly conical with the apex between the posterior seventh and eighth of the length of the valve; the slope from the apex to the posterior margin is about 45° and to the front at a low angle after passing from the steeper slope adjoining the apex. On each side of the apex there is an elongate, sharp tubercle, and just back, a minute pedicle opening. A slightly outlined triangular false area begins at the pedicle opening and extends to the posterior margin; it is divided by a faint, narrow, rounded ridge. Dorsal valve moderately convex, with the umbo broad, and beak at the posterior margin.

The exterior surface is marked by concentric lines of growth that cross the area of the ventral valve. The ventral valve has numerous low, narrow, obscure radiating ridges, and an extremely minute series of irregular, concentric, inosculating elevated lines that give the surface a roughened appearance under a strong lens.

Substance of the shell in appearance corneous. The largest shell in the collection is represented by a dorsal valve; this has a length of 6 mm.; width, 7 mm.

The casts of the interior of the ventral valve are very good; they show that the shell was thick over the umbo, that the cast of the pedicle opening was cone-shaped (Pl. LVIII, fig. 5b), and that on each side just in front of the base of the opening there was a short, narrow depression corresponding in position to the tubercles on the outer surface. Back of the cast of the opening the false area is rather strongly defined, also the cast of the hollows occupied by the cardinal muscles; the main vascular sinuses originate just back of the pedicle opening and arch forward toward the anterolateral margins of the shell (Pl. LVIII, fig. 5e); usually they have left no impression on the shell in advance of the visceral area; the visceral area is short and fairly well defined on some specimens (fig. 5d). Nothing is known of the muscle scars of the ventral valve except the position of the cardinal scars.

The cast of the interior of the dorsal valve is most interesting, as a true area similar to that of *Acrotreta definita* Walcott (Pl. LXIV, fig. 2d) and *Acrotreta kutorgai* Walcott (Pl. LXV, fig. 3j) is clearly shown; the area is short and divided midway by a triangular space, the lateral, slightly elevated sides of which project a little into the valve beyond the front margin, very much as in *Obolella atlantica* Walcott (Pl. LV, fig. 1e) and *O. crassa* (Hall) (Pl. LIV, fig. 2g). A median ridge extends from in front of the area to the anterior third of the valve; it has a narrow, low, median septum on its posterior half, and two central muscle scars (h) on its outer slopes a little back of the center of the valve; the anterior lateral muscle scars (j) are a little in

advance of the centrals, close to the median ridge and smaller than the centrals; the main vascular sinuses are very faint beyond where they come forward into the body of the valve; back toward the posterolateral margin of the valve small cardinal scars occur at about the same distance from the center of the area as the central scars are in front of it.

Observations.—This species is so strongly marked in its ventral valve by the pointed tubercles beside the apex, the cone-shaped pedicle passage through the shell, and distinct visceral area, and in the dorsal valve by a well-defined area and small cardinal muscle scars far out on the cardinal slope, that it can not readily be confused with any known species.

FORMATION AND LOCALITY.—Middle Cambrian: (94x) Shales 0.06 mile (0.1 km.) south of Givens Mill, Cowan Creek, about 8 miles (12.8 km.) southeast of Center; and (90x) *in and attached to the outer surface of siliceous nodules in the Conasauga ("Coosa") shale, Coosa Valley, east of Center; both in Cherokee County, Alabama.*

ACROTHELE BERGERONI Walcott.

Plate LVIII, figures 6, 6a-c.

- La Discina* MIQUEL, 1894, Note sur la Géologie des Terrains Primaires du Département de l'Hérault, le Cambrien et l'Arenig, p. 10. (Mentioned in French.)
- La Discina* MIQUEL, 1895, Bull. Soc. d'Étude Sci. Nat. Béziers for 1894, Mém. Compt. Rend. des Séances, vol. 17, 1895, p. 10. (This article is a copy of the preceding reference which was published as a separate.)
- Acrothele* ПОМРЕКЪ (in part), 1896, Jahrb. K.-k. geol. Reichsanstalt for 1895, Bd. 45, Hft. 3, p. 603. (Discussed in German, changing generic reference; see under *Boisfordia? barrandei*, p. 603, for copy.)
- Acrothele bergeroni* WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 3, pp. 83-84, Pl. VIII, fig. 11. (Described and discussed as below as a new species. Fig. 11 is copied in this monograph, Pl. LVIII, fig. 6c.)

All the specimens representing this species are flattened by compression in the argillaceous shale, also more or less distorted. The outline of figure 6 (Pl. LVIII) is probably the nearest the original outline of the ventral valve, and figure 6c of the dorsal. A ventral valve 6 mm. in length has the apex 1.5 mm. from the posterior margin. A cast of the interior of a ventral valve (Pl. LVIII, fig. 6b) indicates a relatively large interior opening for the pedicle tube; a short, small visceral cavity with the shell thickened so as to form a short ridge; and an obscure false area; also that the posterior margin is arched slightly above the plane of the margin of the valve. An exterior cast shows the impression of a minute elongate tubercle on each side of the apex, and a small pedicle opening just back of them. A cast of the interior of a dorsal valve shows a short median ridge, and the posterior portion of the main vascular sinuses.

The exterior cast shows that the surface was marked by small concentric ridges and lines of growth, a few low, obscure, rounded, radiating ridges, and fine granulations or tubercles on very minute, irregular, more or less inosculating concentric ridges, or the same type of surface as that of *Acrothele coriacea* Linnarsson. If these shells were found at the same horizon in Sweden as *A. coriacea* I think they would be referred to that species except that the apex of the ventral valve of the French species is much nearer the posterior margin; more perfect specimens would probably show other differences.

This species appears to differ from *Acrothele quadrilineata* Pompeckj and *A. bohémica* (Barrande) by the more anterior position of the apex of the ventral valve.

In response to a request for permission to study the Cambrian brachiopods that he had collected from Montagne Noire, Mr. Miquel very courteously sent me a number, and among them I found this species, and, with his permission, have described it.

It gives me pleasure to give the specific name in recognition of the discovery by Prof. J. Bergeron of the Middle Cambrian fauna of Hérault, and his fine work on the fauna.

FORMATION AND LOCALITY.—Middle Cambrian: (342 [Miquel, 1893, p. 9]) Shales in Montagne Noire, Coulouma, Department of Hérault, France.

ACROTHELE BOHEMICA (Barrande).

Plate LVII, figures 1, 1a-d.

Obolus? bohemicus BARRANDE, 1879, *Système silurien du centre de la Bohême*, vol. 5, pt. 1, Pl. CII, figs. VII: 1-3. (Not described, but figured as a new species. Figs. VII: 1-2 are reproduced in this monograph, Pl. LVII, figs. 1 and 1a, respectively.)

Acrothele bohémica (Barrande), WALCOTT, 1886, *Bull. U. S. Geol. Survey No. 30*, p. 107. (Merely changes generic reference.)

Acrothele bohémica (Barrande), HALL and CLARKE, 1892, *Nat. Hist. New York, Paleontology*, vol. 8, pt. 1, p. 101. (Suggests reference to *Acrothele*.)

Acrothele bohémica (Barrande), POMPECKJ, 1896, *Jahrb. K.-k. geol. Reichsanstalt for 1895*, Bd. 45, Hft. 3, pp. 509-511, Pl. XIV, figs. 7-15. (Described and discussed in German. Figs. 8b, 11b, and 10b are reproduced in this monograph, Pl. LVII, figs. 1b, 1c, and 1d, respectively.)

Barrande did not publish a description of this species, but Pompeckj [1896b, p. 509] gives an extended description based on a large number of specimens. From this and the accompanying illustrations it appears that the general form is much like that of *Acrothele coriacea* Linnarsson. It differs from the latter in having the apex nearer the posterior margin and in having a concentrically striated surface and undulating lines instead of granulose surface; these characters also distinguish *A. bohémica* from *A. (Redlichella) granulata* (Linnarsson). The student should carefully examine the series of figures accompanying Pompeckj's description as well as those of Barrande. Copies of the latter are inserted on Plate LVII, figures 1 and 1a, and copies of Pompeckj's figures on Plate LVII, figures 1b, 1c, and 1d.

The posterior position of the apex of the ventral valve suggests in this respect *Acrothele prima* (Matthew) (Pl. LXI, fig. 6) and *Acrothele prima costata* (Matthew) (Pl. LXI, figs. 4 and 4a), but in surface characters and outline of the valves the species differ, as indeed they do in the apex of *A. prima* being nearer the margin than that of *A. bohémica*. Comparison should be made with *A. quadrilineata* Pompeckj, which is closely allied to this species.

The specific name is derived from Bohemia.

FORMATION AND LOCALITY.—Middle Cambrian: (345 [Pompeckj, 1896b, p. 509]) Greenish shale in the *Paradoxides* zone, on the Dlouhá Hora, above the brook of Sbírov, near Skrej; (345a [Pompeckj, 1896b, p. 511]) shales in the *Paradoxides* zone, on the right bank of the brook of Karásek, near Tejšovik; (345b [Pompeckj, 1896b, p. 511]) in the "Bande de Jinec," at Felbabka and Jinec; and (345c) in *Étage C* [Barrande, 1879b, Pl. CII], at Mleschitz; all in Bohemia, Austria-Hungary.

ACROTHELE BORGHOLMENSIS Walcott.

Plate LXIII, figures 2, 2a-b.

Acrothele borgholmensis WALCOTT, 1908, *Smithsonian Misc. Coll.*, vol. 53, No. 3, pp. 84-85, Pl. VIII, fig. 12. (Described and discussed as below as a new species. Figs. 12 and 12' are copied in this monograph, Pl. LXIII, figs. 2 and 2a, respectively.)

General form subcircular to broad oval. Ventral valve subconical, with the apex a short distance back of the center. A clearly defined false area extends from the apex to the margin; it is defined by a slight depression and a low ridge at the outer edges; two or three longitudinal lines extend to the margin, and the concentric lines of growth of the shell cross it without interruption. An elongate, small foraminal aperture occurs just back of and beneath the apex.

The outer surface of the shell is of a dull, dark color, and marked by slightly undulating, clearly defined, concentric striæ; the inner layers are marked by fine radiating and concentric lines. The shell is built up of thin lamellæ arranged in concentric layers that are slightly oblique to the surface layer. Shell substance corneous. Nothing is known of the interior of the valves except the sharp median ridge of the dorsal valve.

The largest specimen has a diameter of 4 mm.; the average size is about 3 mm.

Observations.—The convexity, position of the apex, and clearness of the false area depend upon the degree of compression and distortion the shells have received. I have described what appears to be the uninjured shell.

The subcentral position of the apex seems to distinguish this species. It is associated with *Obolus* (*Bröggeria*) *salteri* (Holl) and *Lingulella lepis* (Salter).

The specific name is derived from Borgholm, the type locality.

FORMATION AND LOCALITY.—Upper Cambrian: (310d) *Ceratopyge* slate at Borgholm, Oeland Island, Sweden.

ACROTHELE CERATOPYGARUM (Brögger).

Plate LXIII, figures 1, 1a-c.

Discina (*Acrotreta*?) *ceratopygarum* BRÖGGER, 1882, Die silurischen Etagen 2 und 3, p. 47, Pl. X, figs. I, 1a-b. (Described in German. Figs. 1a and 1b are reproduced in this monograph, Pl. LXIII, figs. I and 1a, respectively.)

Acrothele ceratopygonum WALCOTT, 1902, Proc. U. S. Nat. Mus., vol. 25, p. 598. (Mentioned in discussion of *Acrotreta seebachi*.)

Acrothele ceratopygarum (Brögger), MOBERG and SEGERBERG, 1906, Medd. från Lunds Geol. Fältklubb, Ser. B, No. 2 (Aitryck ur K. Fysiografiska Sällskapets Handl., N. F., Bd. 17), p. 67. (Mentioned in Swedish.)

Acrothele barbata MOBERG and SEGERBERG, 1906, idem, pp. 67-68, Pl. III, figs. 7-10. (Described and discussed in Swedish as a new species.)

Ventral valve conical, with eccentric apex. False area well defined and marked midway by a narrow, slightly elevated ridge that does not extend quite to the margin of the shell; on the interior of the shell a narrow furrow extends nearly to the margin where it is cut off by a transverse ridge just within the margin. Foraminal aperture minute, situated at the top of the false area just below the apex; in the exfoliated shell it appears to be elongate. The outer surface of the shell appears in a cast to be nearly smooth; the inner layers or lamellæ are marked by fine concentric and radiating lines. A cast of the interior shows a very small visceral area just in front of the apex, and a cardinal muscle scar on each side of the median line back of the cast of the foraminal opening. The two ventral valves measure 5 mm. in diameter; height, about 2 mm.

From Moberg and Segerberg's description [1906, p. 67] of the dorsal valve of *Acrothele barbata* the following is taken: "The dorsal valve is nearly flat, or with the posterior and central parts slightly arched; beak marginal." The interior shows a few traces of muscle scars. The interior of the ventral valve shows the main vascular sinuses and branches very much as in *Acrothele coriacea* Linnarsson (Pl. LVI, figs. 1a, 1d). These authors give the dimensions of one of the larger shells as, length, 5.25 mm.; width, 6 mm.; elevation, 1.5 mm.

Observations.—Through the courtesy of Doctor Brögger I have had the opportunity of studying the type specimens of this species. One of them is illustrated (Pl. LXIII, fig. 1c), and I have also copied two of Brögger's figures. The species is related to *Acrothele borgholmensis* Walcott from the *Ceratopyge* slate, but differs in the character of the false area and median ridge of the latter. It is also a larger and more convex form.

Specimens from Vestfossen, Norway, one of which is illustrated on Plate LXIII, figure 1b, have the same form as the shells described by Moberg and Segerberg under the name of *Acrothele barbata* [1906, p. 67], and I find bits of the outer shell showing the "coarse, irregular, anastomosing, concentric ridges" characteristic of *Acrothele barbata*; a little trace of the marginal fringe is also shown on one specimen. The fact that the two species occur at the same stratigraphic horizon in Sweden and Norway, and the fact that they have the same specific characters, lead me to place *A. barbata* as a synonym of Brögger's *A. ceratopygarum*.

This species derives its specific name from its occurrence in the *Ceratopyge* limestone.

FORMATION AND LOCALITY.—Passage beds between the Upper Cambrian and the Ordovician: (323h [Brögger, 1882, p. 17]) blue *Ceratopyge* limestone, at Vestfossen, 10 miles (16.1 km.) west-southwest of Christiania, Norway.

(310 [Moberg and Segerberg, 1906, p. 67]) *Ceratopyge* limestone (zone 4), at Ottenby, on Oeland Island, Sweden.

ACROTHELE COLLENI n. sp.

Text figures 55A-E, page 641; Plate LXIII, figures 6, 6a-b.

This species is represented by numerous specimens of both valves, but only the exterior of the valves is known. The ventral valve is subconical, with the apex a little in front of the

posterior third; the slope from the apex to the posterior margin is about 45° and that to the anterior margin 20° . The posterior slope is marked by a rather clearly defined false area, which is slightly flattened, and marked midway by a very slight depression; the apical opening is small, oval in outline, and situated on the posterior side of the apex. On finely preserved specimens the front and sides of the apical opening have a narrow, slightly elevated ridge, and a trace of a small tubercle on each side at the anterior end of the opening; the posterior margin arches very slightly beneath the false area. The dorsal valve is moderately convex, and most prominent on the umbo, with the apex at the posterior margin.

One of the largest ventral valves has a length of 9 mm.; width, 10 mm. The dorsal valve has a length of 7 mm.; width, 8 mm. These proportions vary somewhat as the shells are more or less distorted by compression in the shale. Shell substance corneous.

The exterior surface is marked by very fine, concentric ridges of growth, with depressed and elevated lines between them; there are also numerous low, rounded, narrow, radiating ridges that vary in strength and number on different specimens; on some shells there is hardly a trace of the radiating ridges, and on others they are numerous, especially on the sides: one dorsal valve shows nine on each side, with a few scattered through the central portion in addition to the concentric and radiating lines; there is also a system of exceedingly minute and irregular, more or less inosculating, but, as a whole, concentric ridges, upon which very minute tubercles occur. These are most perfect over the posterior half of the shell, but extend in many examples to the front margin.

A cast of the apical portion of the dorsal valve shows that the pedicle aperture enlarged as it passed through the shell, and that the visceral area was short.

Observations.—This species is of the *Acrothele coriacea* Linnarsson type. It has the same surface, except that the irregular, concentric ridges and tubercles are finer.

FIGURE 55.—*Acrothele coleni* n. sp. A, Slab showing a ventral and a dorsal valve (U. S. Nat. Mus. Cat. No. 51410a). B, Broken ventral valve showing false area (U. S. Nat. Mus. Cat. No. 51410b) (\times about 4). C, A much larger ventral valve than that represented by B (U. S. Nat. Mus. Cat. No. 51410c). D, Cast of a ventral valve showing the incurving of the flexure lines across the false area (U. S. Nat. Mus. Cat. No. 51410d) (\times about 4). E, Dorsal valve (U. S. Nat. Mus. Cat. No. 51410e).

The specimens represented are from Locality 35c, a drift block of Lower Cambrian shales, on the slopes of Mount Bosworth, on the Continental Divide, 1 mile (1.6 km.) east of Hector, British Columbia.

The Lower Cambrian specimens from British Columbia appear to be identical with those from Montana and they are associated with the same subfauna, of which *Albertella helena* Walcott is considered to be typical. The shells from the Middle Cambrian, which occur 2,450 feet higher in the section on Mount Stephen, have the same form and surface markings and appear to be identical in all respects. It is interesting to note that *Micromitra* (*Iphidella*) *pannula* (White) has a similar vertical range.

The specific name is given for Mr. M. Collen, of White Sulphur Springs, Montana, who collected the finest specimens at the locality on Scapegoat Mountain, Montana.

FORMATION AND LOCALITY.—**Middle Cambrian:** (14s) About 2,300 feet (701 m.) above the Lower Cambrian and 2,700 feet (823 m.) below the Upper Cambrian, in the *Ogygopsis* zone of the Stephen formation [Walcott, 1908f, p. 210], on the northwest slope of Mount Stephen, above Field on the Canadian Pacific Railway, British Columbia, Canada.

(4q) About 315 feet (96 m.) above the unconformable base of the Cambrian and 190 feet (57.9 m.) above the top of the quartzitic sandstones, in a shale which corresponds in position to the upper part of shale No. 6 (Lower Cambrian) of the Dearborn River section [Walcott, 1908f, p. 202] on the ridge between Gordon and Youngs creeks, about halfway between Gordon Mountain and Cardinal Peak, Ovando quadrangle (U. S. Geol. Survey), Powell County, Montana.

Lower Cambrian: (57e) About 115 feet (35 m.) below the Middle Cambrian, in limestone correlated with the top of 1c of the Mount Whyte formation on Mount Bosworth [Walcott, 1908f, p. 213], just above the tunnel on the north shoulder of Mount Stephen, about 3 miles (4.8 km.) east of Field, British Columbia; (35e) drift blocks supposed to have come from the Mount Whyte formation [Walcott, 1908f, p. 214], found on the south slope of Mount Bosworth, a short distance northwest of the Canadian Pacific Railway track between Stephen and Hector, eastern British Columbia; and (35e) about 270 feet (82.3 m.) below the Middle Cambrian, in a greenish siliceous shale correlated with No. 3 of the Mount Whyte formation on Mount Bosworth [Walcott, 1908f, p. 214], in the amphitheater between Popes Peak and Mount Whyte, about 3 miles (4.8 km.) northwest of Lake Louise, southwest of Laggan on the Canadian Pacific Railway, Alberta, Canada.

(4v) About 200 feet (61 m.) above the unconformable base of the Cambrian and 75 feet (22.9 m.) above the top of the quartzitic sandstones, in a shale which corresponds in stratigraphic position to shale No. 6 of the Dearborn River section [Walcott, 1908f, p. 202], on Gordon Creek, 6 miles (9.6 km.) from South Fork of Flathead River, Ovando quadrangle (U. S. Geol. Survey), Powell County, Montana.

ACROTHELE CORIACEA Linnarsson.

Plate LVI, figures 1, 1a-i.

Acrothele coriacea LINNARSSON, 1876, Bihang till K. svensk Vet.-Akad. Handl., Bd. 3, No. 12, pp. 21-23, Pl. IV, figs. 44-48. (Described and discussed in English as a new species.)

Acrothele coriace Linnarsson, BRÖGGER, 1878, Nyt Magazin for Naturvidenskaberne, Bd. 24, Hft. 1, p. 76, Pl. IV, fig. 11. (Mentioned.)

Acrothele coriacea Linnarsson, GRÖNWALL, 1902, Danmarks geol. Undersøgelse, Række 2, No. 13, p. 40. (Localities mentioned in Norwegian.)

General form subcircular to transversely broad oval in outline, with the posterior margin slightly transverse. Ventral valve slightly conical with the apex usually within the posterior fourth of the distance from the front to the back margin. The apex, as usually seen, is formed of two minute, elongated tubercles with a narrow, elongate depression between them; at the posterior end of this depression a minute pedicle aperture occurs; on some shells the two minute tubercles unite in front so as to form a ring with a break at the back side just behind which the pedicle aperture opens. The size of the tubercles and median depression varies in different shells, and also with the amount of exfoliation of the outer shell. In some examples when the shell is nearly all exfoliated at the apex and umbo the two tubercles are prominent and a third tubercle occurs back of them which is the cast of the inner portion of the foraminal tube. A narrow false area is faintly defined on some shells and more distinctly on others. A median line often extends from the foraminal aperture to the margin. Casts of the interior show a much more distinctly defined false area, also that it is impressed in the shell. The striæ of growth cross the area without interruption except as they curve slightly upward at the center on some shells. Linnarsson [1876, p. 21] states that there is no trace of a longitudinal groove as in *Acrotreta subconica* Kutorga; this is true of most specimens, but on others from the *Paradoxides forchhammeri* zone, I find a narrow line and on others a curving upward of the concentric striæ at the median line. The dorsal valve is slightly convex near the umbo, from which it curves rather abruptly down to the posterior margin and in some shells the lateral and anterior margins curve up a little, leaving a slightly concave surface between the margins and the umbo. The apex is near the posterior margin; it is divided midway by a narrow furrow so as to form a narrow elongate tubercle on each side. On some shells a slight depression or flattening extends to about the middle of the valve.

The exterior surface is marked by concentric lines and striæ of growth and slight undulations or ridges on the older shells; a few rather faintly indicated, radiating costæ occur on some examples of the ventral valve. Linnarsson [1876, p. 21] describes the outer surface as being rough, somewhat like leather. With a strong magnifier I find this to be caused by a minute granulation on fine, irregular, slightly elevated striæ. The shiny inner layers of the shell are marked by concentric lines and very fine radiating lines.

The shell is corneous and built up of numerous thin layers or lamellæ so as to form a shell that is strong at the umbo and thin toward the margins. The largest ventral valve in

the material available has a length of 8 mm. and a width of 10 mm. The average size is from 5 to 6 mm. in length, with a greater width.

The interior of the ventral valve shows a rounded, slightly depressed visceral area, which forms a semicircular area about the well-defined apical callosity and pedicle opening; back of the latter the false area is usually clearly defined. From each side and a little back of the pedicle opening in the ventral valve a rather strong main vascular sinus arches outward and then forward to the anterior half of the valve, where it divides into two or more branches; numerous lateral sinuses branch off and extend nearly to the margin, and a few shorter branches extend toward the central section. In the dorsal valve the vascular markings include the main vascular sinuses, which extend obliquely forward and outward, and an elaborate series of canals that originate in advance of the visceral area (Pl. LVI, figs. 1d and 1f).

Our information as to the muscle scars of the ventral valve is limited to a suggestion of small cardinal scars on each side of the false area a little back of the main vascular sinuses. In the dorsal valve small cardinal scars (cl) occur on each side of the median ridge back of the base of the main vascular sinuses; small centrals (h) also occur on each side near the anterior end of the median ridge.

Observations.—The above description is made from the study of a large number of specimens from several localities in Sweden, and a fine locality on Bornholm Island, Denmark. It differs somewhat from Linnarsson's [1876, p. 21], chiefly as the result of my having more and somewhat better preserved material for study. He describes an umbonal muscle scar in the dorsal valve, but from his illustration [1876, Pl. IV, fig. 48b] I am inclined to think that the scar is only a bit of the false area, the inner shell having been exfoliated.

The relations of the species are with *Acrothele* (*Redlichella*) *granulata* (Linnarsson), from which it differs in smaller average size, more finely granulated surface, and, what is of more value, in the form of the muscle scars of the dorsal valve.

This type of *Acrothele* is widely distributed. It is represented in Bohemia by *A. bohémica* (Barrande) and *A. quadrilineata* Pompeckj; in France by *A. bergeroni* Walcott; in North America by *A. matthewi* (Hartt) and its varieties; and in China by *A. matthewi eryx* Walcott.

FORMATION AND LOCALITY.—**Passage beds** between the Upper Cambrian and the Ordovician: (8x) Limestone at Slemmestad, about 3 miles (4.8 km.) southwest of Christiania, Norway.

Upper-Middle Cambrian: (310i) Passage beds between the Middle Cambrian *Paradoxides forchhammeri* zone and the Upper Cambrian *Olenus truncatus* zone at Borgholm, Oeland Island, Sweden.

Middle Cambrian: ^a (16h and 334h) Limestones of *Paradoxides forchhammeri* zone at Borregaard; (161) limestones of *Paradoxides davidis* zone at Borregaard; (334b) ^b Andrarum limestone at Borregaard; (334c) ^b in the *Paradoxides tessini* zone at Borregaard; (334d) ^b in the zone with *Agnostus parvifrons* at Borregaard; (334f) limestone on Bornholm Island; (16j) limestone of *Paradoxides forchhammeri* zone at Laesaå; (16k) limestones of *Paradoxides davidis* zone at Laesaå; (334e) Andrarum limestone at Laesaå; all on Bornholm Island, Denmark.

(8w) Limestones of the *Paradoxides forchhammeri* zone, at Andrarum, 20 miles (32 km.) northwest of Simrishamn, Province of Christianstad; (320o) ^c limestone band between the *Holmia kjerulfi* zone and the *Paradoxides tessini* zone at Andrarum, 20 miles (32 km.) northwest of Simrishamn, Province of Christianstad; (320f) limestone at Andrarum, 20 miles (32 km.) northwest of Simrishamn, Province of Christianstad; (3201) drift blocks from the *Paradoxides olandicus* zone at Lillviken, near Oestersund, Jemtland; (320m) ^c limestones of the *Paradoxides forchhammeri* zone at Kinnekulle, northeast of Lidköping, Province of Skaraborg; (320n) limestones of the *Paradoxides forchhammeri* zone at Lovened, Djupadal, 19 miles (30.6 km.) south-southeast of Skara, Province of Skaraborg; (321q) limestones of the *Paradoxides forchhammeri* zone at Munkesten, north of Hunneberg, Province of Skaraborg; (320r) limestones of the *Agnostus lævigatus* zone, at Hunneberg, western boundary of the Province of Skaraborg; (320y) limestones of the *Paradoxides forchhammeri* zone at Gudhem, 12.5 miles (20.1 km.) south-southeast of Skara, Province of Skaraborg; (320b) limestone forming 2d of the *Paradoxides* zone, the *Agnostus lævigatus* horizon, at Gudhem, 12.5 miles (20.1 km.) south-southeast of Skara, Province of Skaraborg; (320v) ^c in the *Paradoxides forchhammeri* zone at Lanna, Hjulsta, Vinala, and Vrana, all four in Nerike; (320p) ^c limestones of the *Paradoxides forchhammeri* zone at Södra Möckleby, southern part of Oeland Island; (320g) limestones of the *Paradoxides forchhammeri* zone at Borgholm, Oeland Island; and (320q) limestone forming 2c of the *Paradoxides forchhammeri* zone, at Alunbruk (alum works), southern part of Oeland Island; all in Sweden.

(324b) Shales of Étage 1c [Brögger] at Krekling, in Sandsvär; (324c) shales of Étage 1d at Krekling, in Sandsvär; and (324a) shale of Étage 1c [Brögger] at Skrena, Skiensdalen; all [Christiania Univ. Min. Inst. Coll.] in Norway.

^a This species also occurs in Locality 320k.

^b Grönwall, 1902, p. 40.

^c Linnarsson, 1876, p. 23.

ACROTHELE DECIPIENS Walcott.

Plate LVIII, figures 3, 3a-d.

Acrothele decipiens WALCOTT, 1897, Proc. U. S. Nat. Mus., vol. 19, p. 716, Pl. LX, fig. 2. (Described and discussed as a new species. The specimen represented by fig. 2 is redrawn in this monograph, Pl. LVIII, fig. 3a.)

General form of the ventral valve subcircular, usually a little longer than wide; moderately convex; apex at the posterior one-sixth to one-eighth of the valve. Pedicle aperture of medium size, situated on the posterior slope of the summit of the apex; the slope from the apex to the posterior margin is rather abrupt; and very gentle to the front margin. The obscure false area, with a faintly defined groove down its center, is shown on some specimens. Dorsal valve oval, moderately convex, and marked by a shallow depression extending from the back to the front; apex marginal.

Surface marked by fine, concentric lines of growth, and very fine, somewhat irregular, and sometimes inosculating ridges upon which occur exceedingly minute tubercles which give a very finely tuberculated surface; some specimens show depressed, narrow, rounded ridges extending from near the apex to the margins; these ridges vary in size and number. Shell substance corneous.

Nothing is known of the interior of the ventral valve except a cast of the apical callosity (Pl. LVIII, fig. 3a). The interior of the dorsal valve has a strong median ridge that extends forward beyond the center, and strong cardinal scars.

Observations.—This species is of the *Acrothele matthewi* (Hartt) type. It has a similar surface, and the apex of the ventral valve is well toward the posterior margin. The interior of the dorsal valve suggests that of *Acrotreta* more than do most interiors of the dorsal valves of *Acrothele*. It has an unusually long and strong median ridge and cardinal muscle scars.

Acrothele decipiens was found associated with fragments of *Olenellus* in the fine gray limestone in the Lower Cambrian shale.

FORMATION AND LOCALITY.—Lower Cambrian: (50) *Shaly limestones, 1.125 miles (1.8 km.) north of Stoner, 10 miles (16.1 km.) east-northeast of York*; and (346) limestone and shale a little south of Emigsville; both in York County, Pennsylvania.

ACROTHELE DICHOTOMA Walcott.

Plate LX, figure 2.

Acrothele? dichotoma WALCOTT, 1884, Mon. U. S. Geol. Survey, vol. 8, pp. 14-15, Pl. IX, fig. 11. (Described and discussed as a new species. The specimen represented by fig. 11 is redrawn in this monograph, Pl. LX, fig. 2.)

Acrotreta dichotoma WALCOTT, 1886, Bull. U. S. Geol. Survey No. 30, p. 107. (Suggests reference to *Acrotreta*.)

Acrotreta dichotoma (Walcott), HALL and CLARKE, 1892, Nat. Hist. New York, Paleontology, vol. 8, pt. 1, pp. 100 and 103. (Mentioned.)

Shell of medium size, thin, corneous, nearly circular in outline, the transverse diameter being a little greater than the longitudinal. Ventral valve depressed, discoid, with the apex but slightly elevated above the general plane of the surface and situated about one-third the distance from the posterior to the anterior margin. The apex is exfoliated, but the inner layers show that it was perforate and that in the interior the shell was thickened about the pedicle opening. The slightly depressed area is triangular in form, and extends to the posterior margin, gradually expanding to a width of a little less than its length; it appears to have been quite minute at first, just beneath the apex, and to have been filled in by successive additions of the shell, so that the generally circular outline of the shell has scarcely been broken by the very slight truncation of the posterior margin. The additions to the posterior margin of the false area are crowded together as little transverse ridges with fine striæ between.

The outer portion of the shell is largely exfoliated, but traces of radiating striæ and concentric lines of growth are shown. The latter on the outer portion appear to have been continuous with those crossing the pseudodeltidium. From each side of the apex a narrow, main vascular sinus gently diverges, extending toward the central portion of the shell. Transverse diameter, 7.5 mm.; longitudinal diameter, 6.75 mm.; elevation or convexity, about 0.75 mm.

When describing this species in 1884 I was not aware that a false area was present on some ventral valves of the type species of the genus, and that the supposed muscle scars were the main vascular sinuses. This caused me to question the generic reference.

The ventral valve of *Acrothele dichotoma* has the same general form as *A. subsidua* (White), but it has a thicker shell, and, so far as known, a concentrically striated surface.

FORMATION AND LOCALITY.—Middle Cambrian: (58) Shaly limestone in upper beds of the Secret Canyon shale, east side of New York and Secret canyons, Eureka district [Hague, 1892, Atlas, Eureka County, Nevada.

ACROTHELE GAMAGEI (Hobbs).

Plate LX, figures 5, 5a-c.

Obolella gamagei HOBBS, 1899, Am. Geologist, vol. 23, No. 2, pp. 114-115, figured. (Described, figured, and discussed as a new species.)

Acrothele gamagei (Hobbs), GRABAU, 1900, Occas. Papers Boston Soc. Nat. Hist., No. 4, vol. 1, pt. 3, pp. 615-617; fig. 48, p. 617; Pl. XXXI, figs. 1a-d. (Described and discussed. Fig. 48 is copied from the figure accompanying the preceding reference.)

Acrothele gamagei (Hobbs), SHIMER, 1907, Am. Jour. Sci., 4th ser., vol. 24, pp. 176 and 177. (New locality mentioned.)

Acrothele gamagei (Hobbs), GRABAU and SHIMER, 1907, North American Index Fossils, vol. 1, p. 200. (Characterized.)

General form subcircular to transversely broad oval in outline, with the posterior margin slightly transverse. Ventral valve slightly conical with the apex at about the posterior fifth of the length of the valve; the apex is formed of two elongate tubercles with a slight depression between them; at the posterior end of the depression a small pedicle opening occurs; back of the pedicle opening a more or less indistinctly defined false area extends to the posterior margin; the posterior margin of the valve arches slightly upward.

The dorsal valve is gently convex with posterior portion curving slightly downward so as to fit closely into the upward-curving margin of the ventral valve; beak marginal.

The surface is marked by narrow, concentric undulations of growth, a few obscurely defined, radiating ribs and fine, concentric, irregular, undulating, elevated lines; the latter have numerous minute tubercles on them over the central portions of the shell, and sometimes on the outer lines of the old shells; this results in a finely granulated surface that may be seen with the aid of a strong lens. The concentric lines cross the false area with only slight irregularity. The shell appears to be corneous and built up of several thin layers or lamellæ.

The interior of the ventral valve shows an elongate depression on each side of the apex, a small visceral area, and not very strongly defined main vascular sinuses that originate back of the pedicle opening and curve forward into the body of the valve. The interior of the dorsal valve has a low, rounded, median ridge that extends forward of the center where it bifurcates; a narrow, sharp, median septum occurs on the posterior portion of the ridge; the main vascular sinuses originate near the posterior margin beneath the beak and extend obliquely forward into the valve.

The only muscle scars seen are the elongate, oval central scars of the dorsal valve, which are situated on the slopes of the median ridge back of the transverse center of the valve.

Observations.—As stated by Grabau [1900, p. 615] this is the Massachusetts representative of *Acrothele matthewi* (Hartt) of the St. John formation of New Brunswick. With the additional information afforded by a collection made by William P. Rust for the United States National Museum, the similarity between the two forms is still more striking; they have the same general form, surface, and convexity; but *A. gamagei* attains a larger size and differs in the position of its main vascular sinuses; the latter may be seen by comparing Plate LX, figures 5b and 5c, with Plate XLI, figures 1c and 1d.

The specific name was given in honor of Miss A. O. Gamage, of South Bristol, Maine.

FORMATION AND LOCALITY.—Middle Cambrian: (326b [Grabau, 1900, p. 617]) Braintree slate, below high tide about 100 feet (30.5 m.) east of the quarry at East Braintree, Abington quadrangle (U. S. Geol. Survey); and (5) siliceous shale on Hayward Creek, Braintree, Dedham quadrangle (U. S. Geol. Survey); both in Norfolk County, Massachusetts.

ACROTHELE INTERMEDIA Linnarsson.

Plate LVI, figures 3, 3a-d.

Acrothele intermedia LINNARSSON, 1879, Sveriges Geol. Undersökning, Afhandl. och Uppsatser, Ser. C, No. 35, pp. 25-27, Pl. III, figs. 40-44. (Described in Latin, and described and discussed in Swedish, as a new species. Figs. 40-44 are reproduced in this monograph, Pl. LVI, figs. 3, 3a-d, respectively.)

Acrothele intermedia Linnarsson, GRÖNWALL, 1902, Danmarks geol. Undersøgelse, Række 2, No. 13, p. 39. (Localities mentioned in Norwegian.)

A comparison of the figures of *Acrothele intermedia* on Plate LVI, with those representing *A. coriacea* Linnarsson and *A. (Redlichella) granulata* (Linnarsson) on the same plate, shows very clearly that *A. intermedia* is related in form to both, but that it differs in narrowing proportionately more toward the posterior margin. Linnarsson [1879, p. 26] states that in surface characters it agrees more nearly with *A. coriacea*. The outer surface is described as having numerous fine concentric striae without granules. He gives [1879, p. 26] the dimensions of two ventral valves as "length 8 and 6 mm., width 9.5 and 7 mm., respectively." A dorsal valve 9 mm. in length has a width of 11 mm.

I have not seen the type of this species, or found specimens of it in the collections received from Sweden. Five of Linnarsson's figures are reproduced on Plate LVI. Two of these show a somewhat different position and arrangement of the main vascular canals and branches of the ventral valve than in *A. coriacea* Linnarsson.

FORMATION AND LOCALITY.—Middle Cambrian: (16h) Limestones of the *Paradoxides forchhammeri* zone at Borregaard; and (334a [Grönwall, 1902, p. 39]) limestones of the *Conocoryphe exsulans* zone at Borregaard; both on Bornholm Island, Denmark.

(320h) Shales in the *Paradoxides tessini* zone at Lovened, Province of Skaraborg; (320i) limestones of the *Coronatus* zone, at Andrarum, 20 miles (32 km.) northwest of Simrishamn, Province of Christianstad; (320j) limestones of the *Coronatus* zone, at Gislöf, Province of Malmöhus; and (320k) limestones of the *Coronatus* zone, at Kiviks Esperöd, Province of Malmöhus; all [Grönwall, 1902, p. 39] in Sweden.

(320q) Limestone forming 2c of the *Paradoxides forchhammeri* zone at Alunbruk (alum works), southern part of Oeland Island, Sweden.

Specimens that are rather doubtfully compared with *Acrothele intermedia* occur at the following locality:

Upper Cambrian: (304j [Mason College Coll.]) Lower Stockingford shales, Puxley Park Lane, halfway up the path to the quarry, Atherstone, Warwickshire, England.

ACROTHELE LEVISENSIS Walcott.

Plate LXXXI, figures 12, 12a-b.

Acrothele levisensis WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 3, p. 85, Pl. VIII, fig. 13. (Described and discussed as below as a new species. Fig. 13 is copied in this monograph, Pl. LXXXI, fig. 12.)

Outline transversely broad ovate, ventral valve moderately convex at the apex, which is about the posterior fifth of the length of the valve; pedicle aperture small and situated on the slope back of and near the apex. Dorsal valve depressed convex, with a very gentle slope from the umbo to the front margin and a greater slope to the marginal beak.

Surface marked by fine concentric lines and striae that cross the space back of the apex without apparent interruption. A compressed ventral valve 8 mm. in length has a width of 10 mm. A dorsal valve has a length of 7 mm.; width, 8 mm.

The cast of the interior of a compressed dorsal valve shows a median ridge that expands near the center of the valve, and a main vascular sinus on each side that has the same general course as in *Acrothele coriacea* Linnarsson.

Observations.—In general form this species is much like *Acrothele coriacea* and related species. It differs from them in having a smooth surface except for the concentric lines and striae.

The four specimens representing this species were attached to a block in the collections of the Geological Survey of Canada, with specimens of *Elkania desiderata* (Billings).

The specific name is derived from Point Levis, the type locality.

FORMATION AND LOCALITY.—Lower Ordovician: (319a [Geol. Survey Canada]) Levis shale, Point Levis, Province of Quebec, Canada.

ACROTHELE MACULATA (Salter).

Plate LVII, figures 2, 2a-b; Plate LVIII, figure 2.

Obolella maculata (HICKS MS.) SALTER, 1866, Rept. British Assoc. Adv. Sci. for 1865, p. 285. (Name merely listed.)
Obolella maculata Salter, DAVIDSON, 1868, Geol. Mag., vol. 5, p. 311, Pl. XVI, figs. 1-3. (Described as below, and discussed. Figs. 1-3 are reproduced in this monograph, Pl. LVII, figs. 2, 2a-b, respectively.)

Obolella maculata Salter, DAVIDSON, 1871, British Fossil Brachiopoda, vol. 3, pt. 7, No. 4, p. 341, Pl. L, figs. 18-21. (Copy of preceding reference. Figs. 18, 19, and 21 are copied from Davidson, 1868, Pl. XVI, figs. 1, 2, and 3, respectively.)

Not *Obolella maculata* DELGADO, 1904, Comunicações Comissão Serviço Geol. Portugal, tome V, fasc. 2, p. 364, Pl. IV, fig. 24. (Described in French. This species is referred in this monograph to *Acrothele villaboimensis*.)

The description by Davidson [1868, p. 311] follows:

Shell small, transversely oval, valves moderately convex; 4 lines in length, by 5 in breadth. Beak very obtusely acuminate; front broadly rounded; greatest breadth at about the middle of the shell; surface smooth, marked only by fine concentric lines of growth. Interior incompletely known.

From the above description it is not possible to refer this species to *Acrothele*, but the figure given of the interior of the dorsal valve clearly indicates that genus. All of the figures given by Davidson appear to be of dorsal valves. It would be interesting to know if the specimens illustrated by Davidson [1871, Pl. LIX, figs. 41a, 42a] as "*Discina pileolus* Hicks" are associated with the specimens illustrated as "*Obolella maculata* Hicks" [Davidson, 1871, Pl. L, figs. 18-21].

With our present information it is difficult to make comparisons with other species of *Acrothele* further than to call attention to the similarity of the interior of the dorsal valve to that of *Acrothele subsidua* (White) (Pl. LX, fig. 1k).

FORMATION AND LOCALITY.^a—Middle Cambrian: (318d [Davidson, 1871, p. 341]) Sandstone in the middle portion of the Menevian at Porth-y-rhaw, St. Davids; and (318h) shales in the Menevian at St. Davids; both in South Wales.

(318e) Lower portion of the Menevian, at Camlan; and (318f) lower portion of the Menevian at Gwynfynydd; both [Davidson, 1871, p. 341] in North Wales.

ACROTHELE MATTHEWI (Hartt).

Plate LXI, figures 1, 1a-g.

Lingula matthewi HARTT, 1868, Acadian Geology, by Dawson, 2d ed., p. 644, fig. 221. (Described as a new species.

The specimen represented by fig. 221 is redrawn in this monograph, Pl. LXI, fig. 1a.)

Lingula matthewi HARTT, 1878, idem, 3d ed., p. 644, fig. 221. (Copy of Hartt, 1868, p. 644.)

Acrothele matthewi (Hartt), WALCOTT, 1884, Bull. U. S. Geol. Survey No. 10, p. 15, Pl. I, figs. 4 and 4a. (Original description copied and species discussed. The specimen represented by fig. 4a was labeled by Hartt as "*Obolus (Discina) nitidus*," n. sp., and is redrawn in this monograph, Pl. LXI, fig. 1. Fig. 4 is drawn from the specimen figured by Hartt, 1868, p. 644, fig. 221, and is redrawn in this monograph, Pl. LXI, fig. 1a.)

Acrothele matthewi (Hartt), WALCOTT, 1886, Bull. U. S. Geol. Survey No. 30, p. 109. (Mentioned as similar to *Acrothele subsidua*.)

Acrothele matthewi (Hartt), MATTHEW, 1886, Trans. Roy. Soc. Canada for 1885, 1st ser., vol. 3, sec. 4, No. 4, pp. 39-41, Pl. V, figs. 15 and 15a. (Original description copied and species redescribed and discussed.)

Acrothele matthewi (Hartt), WALCOTT, 1891, Tenth Ann. Rept. U. S. Geol. Survey, p. 609. (Mentioned as closely allied to *Acrothele subsidua* (White).)

Lingula matthewi HARTT, 1891, Acadian Geology, by Dawson, 4th ed., p. 644, fig. 221. (Copy of Hartt, 1868, p. 644.)

Acrothele matthewi (Hartt), HALL and CLARKE, 1892, Eleventh Ann. Rept. State Geologist New York for 1891, Pl. III, fig. 24. (Fig. 24 is drawn from the specimen figured by Matthew, 1886, Pl. V, figs. 15 and 15a.)

Acrothele matthewi (Hartt), HALL and CLARKE, 1892, Nat. Hist. New York, Paleontology, vol. 8, pt. 1, pp. 99 and 100, Pl. III, fig. 29. (Discussed. Fig. 29 is copied from fig. 24 of the preceding reference.)

Acrothele matthewi (Hartt), MATTHEW, 1895, Trans. New York Acad. Sci. for 1894-95, vol. 14, p. 128, Pl. V, figs. 6a-h. (No text reference. Figs. 6a-b are copied from Matthew, 1886, Pl. V, figs. 15 and 15a, respectively.)

Acrothele matthewi (Hartt), MATTHEW, 1902, Bull. Nat. Hist. Soc. New Brunswick, vol. 14, pt. 5, No. 20, pp. 397 and 402, Pl. XVII, figs. 5a-b. (Mentioned. Figs. 5a-b are copied from Matthew, 1886, Pl. V, figs. 15 and 15a, respectively.)

Acrothele matthewi (Hartt), MATTHEW, 1903, Geol. Survey Canada, Rept. Cambrian Rocks Cape Breton, p. 104, Pl. V, figs. 5a-b. (Mentioned. Figs. 5a-b are copied from Matthew, 1902a, Pl. XVII, figs. 5a-b, respectively.)

^aThe type locality is unknown. Davidson's figure 3 [1868, Pl. XVI] has been designated as the type, but its locality is unknown.

Acrothele matthewi (Hartt), GRABAU and SHIMER (in part), 1907, North American Index Fossils, vol. 1, p. 200, fig. 234f (not 234g). (Described. Fig. 234f is copied from Matthew, 1886, Pl. V, fig. 15; fig. 234g from Matthew's figure, 1895a, Pl. V, figs. 7a-b, of *Acrothele matthewi prima*, now referred to *Acrothele prima*.)

General form subcircular to transversely broad ovate in outline, with the posterior margin slightly transverse. Ventral valve subconical in young shells, becoming depressed, with an elevated apex in the adult stages of growth. The apex is within the posterior fourth of the valve, usually about one-sixth the distance from the posterior to the front margins; it is formed of two minute, more or less elongated tubercles, with a depression between them at the posterior end of which a minute pedicle opening occurs; a specimen of the variety *Acrothele matthewi multicosta* Matthew shows a minute tubercle just back of the pedicle opening that looks as though it were part of a ring that formerly extended about the apex, the two side tubercles being other portions of the ring. A narrow false area is indicated on some shells; on others it is absent.

Dorsal valve slightly convex on the umbo, and nearly flat over the anterior portions; apex marginal as far as can be determined from the compressed shells. The exterior surface is marked by concentric lines and striae of growth and a few laminated ridges near the outer margins; on some specimens of the ventral valve one or two low, obscure ridges extend forward from the apex to the front margin. The epidermal layer is also marked by fine granulations or papillae that are thickly placed over the surface; on the outer portions the granules are closely spaced on the top of low, irregular, narrow ridges in the same manner as on *Acrothele coriacea* Linnarsson; the inner layers of the shell are shiny and marked by concentric lines and very fine radiating striae.

The shell is corneous and built up of several thin layers or lamellae. A large ventral valve has a length of 7 mm. with a width of 8 mm.

The interior of the ventral valve shows an apical callosity penetrated by the pedicle opening, and back of it the base of the main vascular sinuses; the latter extend outward and forward to about the transverse center of the valve, and then forward, curving inward more or less; rather strong lateral branches extend outward at varying points; one specimen shows three branches and another seven branches; back of the base of the sinuses a narrow, depressed space extends to the margin of a very narrow area; these features are shown in a cast of the interior (Pl. LXI, fig. 1c); the median depressed space corresponds to the false pedicle furrow in some species of *Acrotreta* (Pl. LXV, figs. 3g, 3h). The interior of the dorsal valve has a very characteristic median septum that extends forward from one-fourth to one-half the length of the valve; also the posterior portions of the main vascular sinuses that originate in front of the beak and extend outward and then obliquely forward.

Of the muscle scars only the minute umbonal scars of the ventral valve have been observed; these are minute and close to the anterior end of the false pedicle furrow.

Observations.—In general form and size *Acrothele matthewi* is allied to *A. coriacea* Linnarsson. The interiors of the valves are also much alike, as may be seen by comparing Plate LVI, figures 1a-c, with Plate LXI, figures 1c and 1d (ventral valves), and Plate LVI, figure 1e, with Plate LXI, figure 1g (dorsal valves). The main vascular sinuses of the ventral valve of *A. matthewi* are stronger than those of *A. coriacea*, and the outer, granular surface of the epidermal layer is also much coarser. *Acrothele matthewi* differs from *Acrothele (Redlichella) granulata* (Linnarsson) in its smaller size and in the markings on the interior of the ventral valve; the granulated outer surface of the two species is similar, the differences between them not being greater than the variations on different portions of the same shell. From *A. avia* Matthew and *A. proles* Matthew this species is separated by the surface characters. It is difficult to institute detailed comparisons of outline and form of *A. matthewi* and other species, as both it and its varieties are represented by compressed and more or less distorted shells.

Acrothele matthewi is a variable species, and Matthew has proposed subspecific names for the most marked of the varieties. One variety (*A. matthewi eryx*) is recognized and named from China. A large form in Matthew's collection labeled "*Acrothele cf. granulata*" appears

to comprise large shells of *A. matthewi*. In the larger shells the granules become coarser toward the outer margins and are more irregularly distributed over the surface.

Of the varieties named by Matthew, "*A. matthewi prima*" appears to be of specific value on account of the position of the apex of the ventral valve. "*Acrothele matthewi costata*" is a variety of *A. prima*, and *A. matthewi multicostata* and *A. matthewi lata* appear to be the only varieties remaining that are sufficiently persistent and definite to be recognized, and even these merge by many gradations into the typical forms of the species.

The specific name was given in honor of Dr. G. F. Matthew.

FORMATION AND LOCALITY.—**Upper Cambrian:** (3) Shaly limestones 300 feet (91.4 m.) above the *Paradoxides* zone, Manuels Brook, Conception Bay, Newfoundland.

Middle Cambrian: (1a, 6n, and 6l) Shales near the top of No. 6; (1) shales of zone A of No. 7; and (2) shales of zone B of No. 7; all in the Manuels Brook section [Walcott, 1891b, p. 261] on Manuels Brook, Conception Bay, Newfoundland.

(6g) Limestone near the base of the Middle Cambrian, the lowest horizon carrying *Paradoxides*, northwest side of Chapple Arm Harbor, about 1 mile (1.6 km.) from its head, Trinity Bay, Newfoundland.

(21 and 2m) Limestones and shales at the base of the *Paradoxides* zone [Matthew, 1895a, p. 108] on Hanford Brook; (301h [Matthew, 1886, p. 41]) shales of Division 1c of Matthew, on Hanford Brook; (301i) beds of Division 1b1 of Matthew, on Hanford Brook; (301j [Matthew, 1886, p. 41]) shales of Division 1d of Matthew, on Porters Brook, St. Martins; (301g [Matthew, 1886, p. 41])^a sandstones of Division 1c of Matthew, at Portland (now part of the city of St. John); (2s) limestone in upper part of *Paradoxides* zone, at Hastings Cove [see Matthew, 1898b, p. 38], on Kennebecasis Bay, 0.5 mile (0.8 km.) northeast of Torryburn, on the Intercolonial Railway, northeast of St. John; (3b) shale at the base of the *Paradoxides* zone, at the head of Seeley Street, St. John; (301k [Walcott, 1884a, p. 16]) shales of the St. John formation at St. John; and (301j [Walcott, 1884a, p. 16]) shales of the St. John formation at Ratcliffs Millstream; all in St. John County, New Brunswick.

ACROTHELE MATTHEWI ERYX Walcott.

Plate LXI, figure 2.

Acrothele matthewi eryx WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 29, p. 11. (Described and discussed as below as a new variety.)

In form, convexity, and size the ventral valve of the only specimen representing this variety is very similar to the typical forms of *Acrothele matthewi* (Hartt). The shell is partly exfoliated and shows a small oval pit about the pedicle opening and two narrow vascular sinuses that extend from a point nearly back of the pit about the pedicle opening, forward, and a little outward, about one-third the length of the valve.

The shell is built up of several layers or lamellæ that are smooth and shiny on the interior, except where slightly roughened by faint vascular markings and obscure radiating striæ; the outer surface is dull and marked by concentric striæ and lines of growth, and numerous fine, irregular, often anastomosing, elevated lines that give the surface a rough appearance.

The ventral valve is nearly circular, with a diameter of 6 mm. If this shell were associated with *Acrothele matthewi* in the Middle Cambrian rocks of New Brunswick, I should not hesitate to identify it with that species. In the absence of a series of specimens, and of representatives of the dorsal valve, it is not certain that it is identical with *Acrothele matthewi*.

FORMATION AND LOCALITY.—**Middle Cambrian:** (C4) Limestone nodules at the base of the lower shale member of the Kiulung group [Blackwelder, 1907a, pp. 37 and 40 (2d list of fossils), and fig. 10 (bed 4), p. 38], 3 miles (4.8 km.) southwest of Yenchuang, Sintai district, Shantung, China.

ACROTHELE MATTHEWI LATA Matthew.

Plate LXI, figure 3.

Acrothele matthewi lata MATTHEW, 1886, Trans. Roy. Soc. Canada for 1885, 1st ser., vol. 3, sec. 4, No. 4, p. 41, Pl. V, figs. 17 and 17a. (Described as a new variety. The specimen represented by figs. 17 and 17a is redrawn in this monograph, Pl. LXI, fig. 3.)

Acrothele matthewi lata Matthew, HALL and CLARKE, 1892, Eleventh Ann. Rept. State Geologist New York for 1891, Pl. III, figs. 25 and 26. (Fig. 26 is drawn from the specimen figured by Matthew, 1886, Pl. V, figs. 17 and 17a.)

^a This species also occurs in Locality 308h.

Acrothele matthewi lata Matthew, HALL and CLARKE, 1892, Nat. Hist. New York, Paleontology, vol. 8, pt. 1, Pl. III, figs. 26-28. (No text reference. Figs. 27 and 28 are drawn from the specimen figured by Matthew, 1886, Pl. V, figs. 17 and 17a. Figs. 26 and 27 are copied from figs. 25 and 26, respectively, of the preceding reference.)

Acrothele matthewi lata MATTHEW, 1895, Trans. New York Acad. Sci. for 1894-95, vol. 14, Pl. V, figs. 8a-b. (No text reference. Figs. 8a-b are copied from Matthew, 1886, Pl. V, figs. 17 and 17a, respectively.)

Acrothele matthewi lata MATTHEW, 1903, Geol. Survey Canada, Rept. Cambrian Rocks Cape Breton, p. 104, Pl. V, figs. 6a-b. (Mentioned. Figs. 6a-b are copied from Matthew, 1902a, Pl. XVII, figs. 6a-b, respectively.)

This variety is characterized by having a flatter rim that gives the valves a depressed appearance around the border. There are many variations that tend to unite it with typical examples of the species, but there is no difficulty in recognizing the typical forms of the variety.

FORMATION AND LOCALITY.—Middle Cambrian: (301 [Matthew, 1886, p. 42]) Sandstones of Division 1b2 of Matthew, on Hanford Brook; (301a [Matthew, 1895a, Pl. V, fig. 8]) *fine-grained sandstones below the Protolenus-bearing shales and sandstones in Division 1b3 of Matthew, on Hanford Brook*; and (301g [Matthew, 1886, p. 41]) sandstones of Division 1c of Matthew, at Portland (now a part of the city of St. John); all in St. John County, New Brunswick.

ACROTIELE MATTHEWI MULTICOSTATA Matthew.

Plate LXI, figures 5, 5a-c.

Acrothele matthewi multicostata MATTHEW, 1897, Trans. Roy. Soc. Canada for 1897, 2d ser., vol. 3, sec. 4, No. 7, p. 168. (Characterized as a new variety.)

This variety is distinguished from the typical forms of the species by the presence of numerous narrow, more or less obscure, radiating ribs. There is a gradation in this respect to typical forms of *A. matthewi*, where an occasional trace of ribs occur. The more anterior position of the apex of the ventral valve serves to distinguish this variety from *A. prima costata*, which occurs at a slightly lower horizon at the same locality.

This form owes its varietal name to the numerous radiating ribs upon its shell surface.

FORMATION AND LOCALITY.—Middle Cambrian: (2s and 2t) *a Shales and interbedded limestone in the upper part of the Paradoxides zone, Hastings Cove [Matthew, 1898b, p. 38], on Kennebecasis Bay, 0.5 mile (0.8 km.) northeast of Torryburn, on the Intercolonial Railway, northeast of St. John*; and (2l) limestone at the base of the *Paradoxides* zone [Matthew, 1895a, p. 108], on Hanford Brook; both in St. John County, New Brunswick.

ACROTIELE? MINUTA Walcott.

Plate LXIII, figure 3.

Acrothele? minuta WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 303. (Described as below as a new species.)

Shell minute, 1.5 mm. in diameter, subcircular in outline, gently convex, with a slight median depression from the umbo to the anterior margin; back of the umbo there is a sharp median depression between minute ridges on each of which there are two points or nipples. Surface marked by fine concentric striae. Substance of shell apparently phosphatic.

This interesting little species is represented by a single specimen. The generic reference is somewhat doubtful.

FORMATION AND LOCALITY.—Middle Cambrian: (C6) Thin slabby limestone in the upper shale member of the Kiulung group [Blackwelder, 1907a, pp. 37 and 41 (2d list of fossils), and fig. 10 (bed 12), p. 38], 2.5 miles (4 km.) southwest of Yenchuang, Sintai district, Shantung, China.

ACROTIELE NITIDA (Ford).

Plate LVIII, figures 4, 4a.

Obolella nitida FORD, 1873, Am. Jour. Sci., 3d ser., vol. 5, p. 213. (Described as on p. 651 as a new species.)

Obolella nitida Ford, WALCOTT, 1886, Bull. U. S. Geol. Survey No. 30, pp. 118-119, Pl. XI, fig. 2. (Original description copied. The specimen represented by fig. 2 is redrawn in this monograph, Pl. LVIII, fig. 4.)

Obolella nitida Ford, WALCOTT, 1891, Tenth Ann. Rept. U. S. Geol. Survey, p. 612, Pl. LXXII, fig. 1. (New localities mentioned. Figure copied from preceding reference.)

Obolella nitida Ford, HALL and CLARKE, 1892, Nat. Hist. New York, Paleontology, vol. 8, pt. 1, p. 70. (Mentioned.)

^a2t is the type locality, though the specimens in the United States National Museum collections to which that number is assigned were collected later than Matthew's type specimens.

Linnarssonia? nitida (Ford), WALCOTT, 1901, Proc. U. S. Nat. Mus., vol. 23, p. 673. (Merely changes generic reference.)
Obolella nitida Ford, GRABAU and SHIMER, 1907, North American Index Fossils, vol. 1, p. 189, fig. 223c. (Described. Fig. 223c is copied from Walcott, 1886, Pl. XI, fig. 2.)

The original description by Ford follows:

Shell transversely suboval, small. Dorsal valve gently but irregularly convex, the greatest elevation occurring at a point about one-fifth the length of the valve from the apex. From this point the beak curves sharply down to the hinge line, which it almost touches. The hinge line itself is slightly curved and apparently equal to about one-third the width of the shell. At the most elevated point of the valve commences a well-defined median depression, which extends forward for a distance of about one-half the length of the valve, gradually widening and becoming more shallow until it disappears. A portion of the dorsal valve close to the margin is sometimes nearly flat all around. The internal markings are not well enough shown in any of the specimens that I have seen to admit of description. The surface is ornamented with very fine concentric striæ and numerous close set radiating striæ, the whole just visible to the unassisted eye.

The ventral valve is not certainly known. The width of the largest dorsal valve that I have seen is 0.14 of an inch and the length 0.1 of an inch.

Through the courtesy of Prof. J. M. Clarke I have had the opportunity of studying the type material of this species, now in the New York State Museum collections. There are four specimens of the dorsal valve and one representing the ventral valve. The reference to *Obolella* [Ford, 1873, p. 213] and *Linnarssonia* [Walcott, 1901, p. 673] is incorrect. The shell is like that of *Acrothele* and the matrix representing the ventral valve shows all the characters of *Acrothele* as far as any characters are shown at all. The slope of the valve toward an eccentric apex is indicated in the same manner as in *Acrothele matthewi* (Hartt).

The only difference detected between this shell and young shells of *Botsfordia cælata* (Hall) is the absence of the characteristic pustulose surface of the latter. Five of Mr. Ford's specimens appear to have come from the same piece of limestone, and nothing that can be identified as the same species has been found in the large collection made at the same locality.

The largest shell has a diameter of 3 mm. The surface is marked by fine concentric striæ, and sharp, interrupted, radiating lines.

FORMATION AND LOCALITY.—Lower Cambrian: (27) *Even-bedded and conglomerate limestones on the ridge in the eastern suburb of Troy, Rensselaer County*; and (22) limestone 1.5 miles (2.4 km.) north of North Granville, Fort Ann quadrangle (U. S. Geol. Survey), Washington County; both in New York.

ACROTHELE PANDERI n. sp.

Plate LIX, figures 5, 5a-c.

This species is of the same general type as *Acrothele colleni* n. sp. It differs in having a less elevated and more posterior apex on the ventral valve, and the finer granulation of the exterior of the shell; also in the presence of a median depression or sinus on the dorsal valve.

The surface is more like that of *Acrothele (Redlichella) granulata* (Linnarsson) as the granulation, although of the same type as that on *A. coriacea* Linnarsson and *A. colleni*, has more the appearance of an epidermal granulated layer.

The description of *A. colleni* applies to this shell with the exceptions mentioned, and a few other details. It also reaches a somewhat larger size. One specimen of the ventral valve has a transverse diameter of 11 mm., with a length of 9 mm. Another example of the same valve has an equal length and breadth; usually the dorsal valve is a little broader than long, and it is marked by a clearly defined median depression that extends from the beak forward, gradually widening to the front margin. The apex of the ventral valve has a minute tubercle on each side, with a small pedicle opening on the slope just back of the tubercles, in this respect closely resembling the apex of *A. coriacea*.

The interior of the ventral valve shows a thickening of the shell under the short visceral area in front of the pedicle opening; the main vascular sinuses appear to originate beside or a little in advance of the pedicle opening and extend forward, gradually separating, but occupying a position about halfway between the margins and the median line.

The specific name is given in honor of Dr. C. H. Pander.

FORMATION AND LOCALITY.—**Lower Cambrian:** (4v) About 200 feet (61 m.) above the unconformable base of the Cambrian and 75 feet (22.9 m.) above the top of the quartzitic sandstones in a shale which corresponds in stratigraphic position to shale No. 6 of the Dearborn River section [Walcott, 1908f, p. 202], Gordon Creek, 6 miles (9.6 km.) from South Fork of Flathead River, Ovando quadrangle (U. S. Geol. Survey); and (5j) the same stratigraphic horizon as 4v, about 6 miles (9.6 km.) west-northwest of Scapegoat Mountain, on the Continental Divide between Bar Creek and the headwaters of the south fork of North Fork of Sun River, Coopers Lake quadrangle (U. S. Geol. Survey); both in Powell County, Montana.

ACROTHELE PRETIOSA (Billings).

Linnarssonina pretiosa (Billings), WALCOTT, 1901, Proc. U. S. Nat. Mus., vol. 23, p. 673. (Merely changes generic reference.)

?*Linnarssonina pretiosa* GRABAU and SHIMER, 1907, North American Index Fossils, vol. 1, p. 200. (Described, but not figured, and it is impossible to tell whether the authors are discussing the *Linnarssonina pretiosa* that is now referred to *Acrotreta sagittalis* or the true *Acrothele pretiosa*.)

General form transversely oval; convexity unknown, as all specimens are more or less flattened in the shale. Ventral valve with the apex near the posterior margin; pedicle aperture small, and at the apex, but whether on its posterior slope or summit can not be determined. Dorsal valve with the beak marginal, and greatest elevation on the umbo on the posterior third of the valve.

Surface marked by numerous concentric lines and striæ of growth and a varying number of irregular, low, narrow, more or less interrupted, radiating ribs; in addition there is a minutely roughened surface formed by very fine, irregular, elevated lines that have minute granules upon them; this results in a surface much like that of *Acrothele matthewi* (Hartt).

The average diameter of the larger specimens is 5 mm., though there are many less than 2 mm. across.

The cast of the interior of a ventral valve shows the cast of a small oval apical callosity; the interior of the dorsal valve has a narrow median ridge that extends forward to the anterior fifth of the length of the valve; the main vascular sinuses are narrow and have the usual direction from the median line near the posterior margin outward and then obliquely forward. The only muscle scars observed are the cardinal scars on each side of the median ridge between the main vascular sinuses and the posterior margin, and the elongate oval central scars in advance of the transverse center of the valve.

Observations.—Owing to the compressed and more or less distorted condition of the specimens representing this species, it is difficult to give an accurate description of it. The posterior position of the apex of the ventral valve, concentrically striated surface, long median ridge in dorsal valve, and position of central scars, give the species an assemblage of detailed characters unknown in other species of the genus.

FORMATION AND LOCALITY.—**Ordovician:** (220a) Shales of the "Upper Sillery" (Lauzon of Logan), on Chaudière River at the Grand Trunk railroad bridge; and (319c [Billings, 1862b, p. 69]) shales at Cape Rouge, above Quebec; both in the Province of Quebec, Canada.

(43) Shales on the summit of Moses Hill, 2 miles (3.2 km.) west of North Greenwich; and (338i) shales 1 mile (1.6 km.) west-northwest of South Argyle; both near the line between the Schuylerville and Cambridge quadrangles (U. S. Geol. Survey), Washington County, New York.

(338z) Limestone on the north side of Bald Mountain, about 2 miles (3.2 km.) northwest of Greenwich, Schuylerville quadrangle (U. S. Geol. Survey), Washington County, New York.

ACROTHELE PRIMA (Matthew).

Plate LXI, figures 6, 6a-b; Plate LXII, figure 2.

Acrothele matthewi prima MATTHEW, 1886, Trans. Roy. Soc. Canada for 1885, 1st ser., vol. 3, sec. 4, No. 4, p. 41, Pl. V, figs. 16 and 16a. (Characterized. The specimen represented by figs. 16 and 16a is redrawn in this monograph, Pl. LXI, fig. 6.)

Acrothele matthewi prima Matthew, HALL and CLARKE, 1892, Eleventh Ann. Rept. State Geologist New York for 1891, Pl. III, fig. 27. (Fig. 27 is drawn from the specimen represented in Matthew, 1886, Pl. V, figs. 16 and 16a.)

Acrothele matthewi prima Matthew, HALL and CLARKE, 1892, Nat. Hist. New York, Paleontology, vol. 8, pt. 1, Pl. III, fig. 25. (No text reference. Fig. 25 is copied from fig. 27 of the preceding reference.)

Acrothele matthewi prima MATTHEW, 1895, Trans. New York Acad. Sci. for 1894-95, vol. 14, Pl. V, figs. 7a-b. (No text reference. The figures are drawn from the specimen represented in Matthew, 1886, Pl. V, figs. 16 and 16a.)

Acrothele matthewi prima MATTHEW, 1902, Bull. Nat. Hist. Soc. New Brunswick, vol. 4, pt. 5, No. 20, pp. 397 and 402, Pl. XVII, figs. 4a-b. (Mentioned. The figures are copied from figs. 7a-b, respectively, of the preceding reference.)

Acrothele matthewi prima MATTHEW, 1903, Geol. Survey Canada, Rept. Cambrian Rocks Cape Breton, p. 104, Pl. V, figs. 4a-b. (Mentioned. Figs. 4a-b are copied from Matthew, 1902a, Pl. XVII, figs. 4a-b, respectively.)

Acrothele matthewi GRABAU and SHIMER (in part), 1907, North American Index Fossils, vol. 1, p. 200, fig. 234g (not 234f). (Described. Fig. 234g is copied from Matthew's figure, 1895a, Pl. V, figs. 7a-b, of *Acrothele matthewi prima*. The specimen represented by fig. 234f belongs with *Acrothele matthewi*, which see, p. 648.)

This species is distinguished from *Acrothele matthewi* (Hartt) by the apex of the ventral valve being almost directly over the posterior margin instead of from one-fifth to one-sixth the length of the valve from it. It has a finely granulated surface of the same type as that of *A. matthewi* and the valves are similar in outline except near the apex of the ventral valve. The average size of this species is a little less than that of *A. matthewi*.

The variety *costata* was separated by Matthew [1895a, p. 128] on account of the presence of six or more ribs; this character is an exceedingly variable one and of little value, as the ribs vary from a faint trace to twenty or more ribs, but as it has been used the varietal name is retained.

FORMATION AND LOCALITY.—Middle Cambrian: (2g)^a Sandstones of Division 1b1; (2f) sandstones 3 feet below 2g in Division 1b1; (2h) sandstones of Division 1b2; and (2i) sandstones of Division 1b3; all in Matthew's [1895a, p. 108] *Protolenus* zone, Hanford Brook, St. John County, New Brunswick.

(13t) Sandstones at the base of Division E1b; and (13d'') sandstones 10 feet (3 m.) below Division E2a; both in Matthew's [1903, p. 21] Etcheminian, Dugald Brook, Indian River, eastern Cape Breton, Nova Scotia.

ACROTHELE PRIMA COSTATA (Matthew).

Plate LXI, figures 4, 4a-d.

Acrothele matthewi costata MATTHEW, 1895, Trans. New York Acad. Sci. for 1894-5, vol. 14, p. 128, Pl. V, fig. 9. (Characterized as a new variety.)

Acrothele matthewi costata MATTHEW, 1902, Bull. Nat. Hist. Soc. New Brunswick, vol. 4, pt. 5, No. 20, p. 397, Pl. XVI, fig. 6. (Mentioned. Fig. 6 is copied from fig. 9 of the preceding reference.)

Acrothele matthewi costata MATTHEW, 1903, Geol. Survey Canada, Rept. Cambrian Rocks Cape Breton, p. 104, Pl. IV, fig. 6. (Mentioned. Fig. 6 is copied from Matthew, 1902a, Pl. XVI, fig. 6.)

Matthew [1895a, p. 128] separated this variety on account of the presence of six or more broad, radiating ribs that are not continuous, but that are interrupted by some of the strong lines of growth; the ribs do not occur on very young shells or near the umbo of the old shells. The surface of the epidermal layer is granulated in the same manner as the typical forms of *A. matthewi* (Hartt).

^a 2g is the type locality, though the specimens in the United States National Museum collections to which that number is assigned were collected later than the type specimens.

The variation in the strength and number of ribs is from a slight trace of one or two short ribs near the front margin to twenty or more ribs. One extreme is represented (Pl. LXI) by figure 4a, and the other by figure 4. The specimens illustrated are from the same layer of rock. *A. matthewi multicosata* Matthew is similar to *A. prima costata* in surface characters and the presence of radiating ribs, but it differs in the more anterior position of the apex on the ventral valve.

The variety *costata* occurs in association with *A. prima* and is distinguished from it by the presence of more or less distinctly indicated ribs.

FORMATION AND LOCALITY.—Middle Cambrian: (2h) Sandstones of Division 1b2;^a (301d [Matthew, 1895a, p. 128]) sandstones of Division 1b5;^a (2i) sandstones of Division 1b3; and (2k) just above 2i, in the sandstones of Division 1b3; all in Matthew's [1895a, p. 108] *Protolenus* zone, Hanford Brook, St. John County, New Brunswick.

(301l [Matthew, 1895a, p. 128]) Sandstones of Division 1d at Porters Brook, St. John County; and (301f [Matthew, 1895a, p. 128]) sandstones of Division 1b5 of Matthew's *Protolenus* zone, at Catons Island, Long Reach, St. John River, Kings County; all in New Brunswick.

(6n) Shales near the top of No. 6 of the Manuels Brook section [Walcott, 1891b, p. 261], Manuels Brook, Conception Bay, Newfoundland.

ACROTHELE PRIMÆVA (de Verneuil and Barrande).

Plate LVII, figure 6.

Discina (Orbicula) primæva DE VERNEUIL and BARRANDE, 1860, Bull. Soc. géol. France for 1859–60, 2d ser., vol. 17, p. 532, Pl. VIII, figs. 2 and 2a. (Described and discussed in French as a new species. Figs. 2 and 2a are reproduced in this monograph, Pl. LVII, figs. 6 and 6', respectively.)

Acrothele primæva (de Verneuil and Barrande), ПОМЕЦКІ, 1896, Jahrb. K.-k. geol. Reichsanstalt for 1895, Bd. 45, Hft. 3, p. 603. (Discussed in German.)

This species appears to have been represented by only the ventral valve; this, the authors state, is corneous, slightly convex, and ornamented by very fine concentric striæ, and three fine lines that radiate from the apex to the front margin. On the figure the apex is about one-third the distance from the posterior to the anterior margin, and a faint false area is indicated by lines that diverge from the apex to the posterior margin.

As far as can be determined from the illustrations and descriptions of the two species, this form is most nearly related to *Acrothele quadrilineata* Pompeckj.

FORMATION AND LOCALITY.—Middle Cambrian: (350 [de Verneuil and Barrande, 1860, p. 538]) Red limestone of the *Paradoxides* zone, near Adrados, north of Sabero and Boñar, Cantabrian Mountains, Province of Leon, north-western Spain.

ACROTHELE PROLES Matthew.

Plate LXII, figures 3, 3a–e, 4, 4a.

Acrothele proles MATTHEW, 1902, Bull. Nat. Hist. Soc. New Brunswick, vol. 4, pt. 5, No. 20, pp. 400–401, Pl. XVII, figs. 3a–e. (Described and discussed as a new species. The specimen represented by fig. 3a is redrawn in this monograph, Pl. LXII, fig. 4. Fig. 4a is drawn from one of Matthew's (unfigured?) specimens.)

Acrothele proles MATTHEW, 1903, Geol. Survey Canada, Rept. Cambrian Rocks Cape Breton, p. 60. (Notes on orientation.)

Acrothele proles MATTHEW, 1903, idem, pp. 102–103, Pl. V, figs. 3a–e. (Description and figures copied from Matthew, 1902a, pp. 400–401, Pl. XVII, figs. 3a–e.)

The most essential difference between this species and *Acrothele avia* Matthew is in the position of the apex of the ventral valve. There are certain minor differences in the visceral callosity, but these are variable and depend more or less upon the state of preservation of the shell. Nearly all the shells of *Acrothele* from the shales and arenaceous beds of the Nova Scotia localities have been distorted by flattening or lateral movement; on this account when one has but a few specimens it is difficult to place confidence on characters subject to change by very slight distortion of the shell.

^a On the description of Plate V [Matthew, 1895a] Matthew says that the type specimen is from divisions 1b2 and 1b5; there is but one type specimen and it can not be ascertained to which of the two divisions it should be assigned. The specimens in the United States National Museum collections from Locality 2h were collected later than the time at which Matthew made his collections.

Acrothele proles has the same type of surface as *A. avia*, also a strong shell that is often thickened in the vicinity of the apex; the number and strength of the radiating ridges vary with the thickness of the shell and the manner in which it has been compressed laterally.

The position of the apex of the ventral valve varies a little, but on the average it is nearer the posterior margin than in *A. avia* and not so near as in *A. prima* (Matthew).

FORMATION AND LOCALITY.—Middle Cambrian: (13m)^a Sandstones of Division E3f in Matthew's [1903, p. 76] Etcheminian, on Gillis Brook, Indian River; and (131') shaly sandstones of Division E3a; and (13n) sandstones of Division E3f; both in Matthew's [1903, p. 21] Etcheminian, on Dugald Brook, Indian River; all in eastern Cape Breton, Nova Scotia.

ACROTHELE QUADRILINEATA Pompeckj.

Plate LVII, figure 5.

Acrothele quadrilineata POMPECKJ, 1896, Jahrb. K.-k. geol. Reichsanstalt for 1895, Bd. 45, Hft. 3, p. 511, Pl. XIV, figs. 6a-c. (Described and discussed in German as a new species; see below for liberal translation. Figs. 6b and 6c are reproduced in this monograph, Pl. LVII, figs. 5 and 5', respectively.)

The original description by Pompeckj follows:

Ventral valve subcircular in outline; length, 7 mm.; width, 7.8 mm.; posterior margin slightly transverse. Apex low and about 2 mm. from the posterior margin; details of apex unknown; false area narrow and indefinitely defined from the apex to the posterior margin. Four flat ridges radiate from the apex toward the front margin. Surface marked by strong, closely arranged, concentric lines that under the microscope show very indistinct granulations. Dorsal valve unknown.

Pompeckj states [1896b, p. 511] that the ventral valve of this species is more arched than that of *Acrothele coriacea* Linnarsson. It is evidently a form closely allied to the latter and also to *Acrothele bohémica* (Barrande), which occurs at the same stratigraphic horizon in the "Paradoxides green slate."

FORMATION AND LOCALITY.—Middle Cambrian: (345d [Pompeckj, 1896b, p. 511]) Shales of *Paradoxides* zone, Forester house of Slapy (Buchava quarry), Skrej, Bohemia.

ACROTHELE RARA Walcott.

Plate LXIII, figures 4, 4a.

Acrothele rarus WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 303-304. (Described and discussed as below as a new species.)

Of this shell only the interiors of the valves are known. Shells of average size are about 3.5 mm. in diameter. The outline of the valves is subcircular, the transverse diameter being slightly more than the length of the valve.

The interior of the ventral valve shows that the valve was moderately convex, with a perforated apex about half a millimeter from the posterior margin. A short, broad median ridge extends for a short distance in front of the foraminal opening, and short, narrow ridges extend obliquely forward from each side of the opening. What may be lateral muscle scars occur close to the posterolateral margins. In the dorsal valve a strong median ridge extends from the posterior margin to the center of the valve; this ridge is angular at the summit and broadest toward its anterior end. A vascular sinus starts on each side of the base of the median ridge and extends obliquely forward.

The dark interior surface of the valves is marked by concentric lines that give a somewhat laminated appearance to the surface. From the manner in which the shell adheres to the limestone matrix it is probable that its outer surface is roughened by raised lines, somewhat as on *Acrothele subsidua* (White).

The data for comparison of this species with described species from America and Europe are too limited to be of value. A comparison with *Acrothele* (*Redlichella*) *granulata* (Linnarsson), of the Salt Range, India, shows a strong similarity in the interiors of the valves, but I do not

^a 13m is the type locality, though the specimens in the United States National Museum collections to which that number is assigned were collected later than the type specimens.

think that it is probable that the two forms are specifically identical, as the interiors of the valves of several species of *Acrothele* appear very much alike.

FORMATION AND LOCALITY.—**Middle Cambrian:** (C57) Limestone nodules in the lower shale member of the Kiulung group [Blackwelder, 1907a, pp. 37 and 40 (first list of fossils)], 3 miles (4.8 km.) south of Kaokiapu and about 4 miles (6.4 km.) north of Sintaihien, Sintai district; and (C23) upper part of thin-bedded gray oolitic limestone at the base of the Changhia formation [Blackwelder, 1907a, p. 32 (list of fossils), and fig. 6 (bed 20), p. 25], 50 feet below the base of the cliffs 1 mile (1.6 km.) east-southeast of Changhia; both in Shantung, China.

ACROTHELE SPURRI Walcott.

Plate LX, figures 3, 3a-c.

Acrothele subsidua WALCOTT (in part) [not WHITE], 1886, Bull. U. S. Geol. Survey No. 30, p. 109, Pl. IX, fig. 4 (not figs. 4a-c). (Locality mentioned in discussion of *A. subsidua*. The specimen represented by fig. 4 is redrawn in this monograph, Pl. LX, fig. 3. Figs. 4a-c belong with *Acrothele subsidua*.)

Acrothele subsidua WALCOTT (in part) [not WHITE], 1891, Tenth Ann. Rept. U. S. Geol. Survey, p. 608, Pl. LXX, fig. 1 (not figs. 1a-c). (Mentioned. Fig. 1 is copied from fig. 4 of preceding reference. Figs. 1a-c belong with *Acrothele subsidua*.)

Acrothele subsidua Walcott, MATTHEW, 1903, Geol. Survey Canada, Rept. Cambrian Rocks Cape Breton, p. 103. (Discussed as possible new species.)

Acrothele spurri WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 3, pp. 86-87, Pl. VIII, fig. 14. (Described and discussed as below as a new species. Fig. 14 is a revised drawing of the specimen represented by fig. 4 of the preceding reference. Fig. 14 is copied in this monograph, Pl. LX, figs. 3, 3a-b.)

General form transversely ovate. Ventral valve depressed with an elevated apex a little in front of the posterior margin; from the apex the surface slopes rapidly and then gradually to the front margin, and quite rapidly to the posterior margin; the posterior margin arches up from the plane of the sides of the valves about one-half the height of the apex and gives to the valve the appearance of being pushed up so as to throw the apex toward the front; a minute pedicle opening truncates the apex at its posterior side; a small, subtriangular, convex false area extends from just back of the apex to the posterior margin.

Surface of the epidermal layer marked by fine, concentric striæ of growth and a very minute granulation; the inner laminations of the shell are shiny and marked by numerous radiating striæ and a few concentric lines. Shell corneous and built up of numerous layers or lamellæ more or less oblique to the outer layer.

Dorsal valve and interior of valves unknown. The largest ventral valve has a length of 6 mm.; width, 7 mm.

Observations.—This very striking species is associated with *Aerotreta primæva* Walcott and *Olenellus gilberti* Meek, in the upper portion of the *Olenellus* zone of central Nevada. Some fragmentary specimens of this species were referred by me [1886b, p. 109] to *Acrothele subsidua* (White), but with better material and more thorough study, the Lower Cambrian specimens are referred to *A. spurri*. *A. spurri* differs from *A. subsidua* in the more posterior position of its apex, in its convex, distinctly marked false area; in its strongly arched posterior margin; and in its more finely granulated surface. The convex false area and arched posterior margin are features also seen in *A. woodworthi* of the Lower Cambrian (Pl. LX, fig. 6).

The specific name is given in honor of Mr. J. E. Spurr.

FORMATION AND LOCALITY.—**Lower Cambrian:** (31a) Limestone and interbedded siliceous shales of the Pioche formation [Walcott, 1908a, p. 11], just above the quartzite on the east side of the anticline, near Pioche, Lincoln County, Nevada.

Specimens that are somewhat doubtfully referred to *Acrothele spurri* Walcott occur at the following locality:

Lower Cambrian: (11) Shales of No. 3 of the Silver Peak group [Walcott, 1908f, p. 189], 2.5 miles (4 km.) south of Barrel Spring and 0.5 mile (0.8 km.) east of the road, in the extreme southeastern corner of the Silver Peak quadrangle (U. S. Geol. Survey), Esmeralda County, Nevada.

ACROTHELE SUBSIDUA (White).

- Acrothele subsidua* (White), GRABAU and SHIMER, 1907, North American Index Fossils, vol. 1, p. 200, figs. 234d-e, p. 199. (Described. Figs. 234d-e are copied from Walcott, 1886b, Pl. IX, figs. 4a-b, respectively.)

General form subcircular to transversely broad oval in outline with the posterior margin broadly rounded to slightly transverse in the dorsal valve. Ventral valve slightly convex toward the apex, with the apex between the posterior one-fifth to one-third the distance from the front to the back margin. The apex when perfect is formed of two minute elongate tubercles with a narrow elongate depression between them; the size and form of the tubercles and depression between them varies; in some specimens the tubercles are united in front, and in others there is a third minute tubercle just back of the apical depression. A pedicle opening varying from a minute circular to a small elongate-ovate aperture, narrow in front, occurs at the posterior end of the apical depression; it may have its narrow end well between the elongate tubercles or back of them. A triangular false area is well defined on some shells, and very obscure on others; it is often divided midway by an elevated line which in some examples is a narrow rounded ridge extending from just back of the pedicle opening to the posterior margin; the concentric striæ of growth cross the area and its median ridge or line without interruption; casts of the interior show the outline of the false area more or less distinctly. The posterior margin is usually slightly arched beneath the false area.

The dorsal valve is depressed convex, with the greatest elevation in front of the posterior margin; the beak is minute, marginal, and divided at the center by an elongate depression that leaves a very minute, slightly elevated, elongate tubercle on each side.

The exterior surface is marked by concentric lines of growth that vary in prominence and strength, and some ventral valves have a few low, rounded, radiating costæ; the costæ differ greatly in length and size, and are entirely absent on many shells. The epidermal layer is ornamented with a minute granulation formed of very minute granules distributed more or less irregularly on irregular raised lines distinct from the concentric striæ of growth, or apparently at times superimposed on the latter. The shiny inner layers of the shell are marked by fine, radiating striæ and concentric lines and narrow radiating depressions corresponding to the external costæ. The shell is corneous and built up of thin layers or lamellæ that give it some thickness over the visceral portions; the inner lamellæ are slightly oblique to the outer surface. The average size of the shells at the typical locality at Antelope Springs is from 5 to 6 mm. in length by 6 to 7 mm. in width; a few miles distant and a little higher in the strata, shells occur 8 to 10 mm. in diameter. Near Montpelier, Idaho, shells from 13 mm. in diameter to young shells 3 mm. in diameter occur in the same bed of shale.

In the interior of the ventral valve a narrow main vascular sinus arches outward from each side a little back of the pedicle opening, and then forward into the anterior half of the valve. The pedicle opening is elongate oval in outline, and has a slightly elevated rim about it and on each side a depression corresponding to the elongate tubercles on the exterior of the shell;

the visceral cavity in front of the opening is short, and in some shells very minute pits along the front indicate muscle scars that are too imperfectly preserved to be identified.

In the posterior half of the interior of the dorsal valve there is a strong median ridge that bifurcates near the center; this ridge enlarges where the central muscle scars (h) occur on its outer slopes and contracts before bifurcating just in advance of the anterior lateral muscle scars (j) (Pl. LX, fig. 1 l). The main vascular sinuses originate near the posterior margin at the end of the median ridge and extend first outward and then obliquely forward as narrow, nearly straight sinuses that are most deeply impressed in the shell at the inner and outer margins. The muscle scars have left very faint impressions on the shell. The cardinal scars (cl) are small and situated at the sharp angle formed by the main vascular sinuses and the posterior margin of the shell (Pl. LX, fig. 1 k). The size and position of the central scars (h) and anterior lateral scars are indicated on Plate LX, figure 1 l.

I have been able to discover no trace of a true area in either valve; the posterior margins of the valves show concentric striæ and often the under side is striated, the surface apparently not having been rubbed against the edge of the opposite valve.

Observations.—There are some noticeable variations in this species, one of which I have separated as the variety *lævis*. In addition there is a variation in the position of the apex of the ventral valve that is often very marked; part of this variation is explained by the compression and consequent distortion of the shells, but there is also a range in the distance of the apex from the posterior margin of about one-fifth to one-third the length of the valve.

Acrothele subsidua lævis is separated on account of the smoother surface of a large group of shells occurring in the Middle Cambrian limestone near Ophir, Utah.

The specimens from the Lower Cambrian of Pioche, Nevada, which I [1886b, p. 109] referred to *Acrothele subsidua* are now referred to *A. spurri*, as more perfect specimens show that although they have the same type of surface the apex of the ventral valve is nearer the posterior margin and the posterior margin is strongly arched below the false area.

A. subsidua is the Cordilleran representative of the Swedish *Acrothele coriacea* Linnarsson and the American Atlantic coast *A. matthewi* (Hartt). It differs from *A. coriacea* in its more finely granulated surface, in the average more anterior position of the apex, in the average more circular outline of the ventral valve, and in the main vascular sinuses and their branches in the ventral valve. From *A. matthewi* it differs in surface characters and interior vascular markings. *A. subsidua* is much like *Acrothele (Redlichella) granulata* (Linnarsson) in form and size, but it differs in not having the strong granulations of the latter species upon its outer surface, also in having different interior vascular markings.

The vertical range of this species in the House Range section is from the lower portion of the Wheeler formation up into the top of the Marjum limestone, a vertical distance of about 1,200 feet. In the shales of the Wheeler formation it is associated with *Asaphiscus wheeleri* Meek, *Ptychoparia kingi* (Meek), and *Agnostus interstrictus* White. In the Marjum limestone this fauna disappears and a new subfauna of the Middle Cambrian fauna appears in which *Obolus mcconnelli* (Walcott) and *Micromitra (Iphidella) pannula ophirensis* (Walcott) occur. At Ophir, in the Oquirrh Range, *Acrothele subsidua lævis* is abundant at about the same horizon as the lower portion of the Marjum limestone. On the west front of the Wasatch Range, in Utah, it is associated with *Obolus mcconnelli* (Walcott) and *Acrotreta ophirensis* Walcott.

FORMATION AND LOCALITY.—Middle Cambrian: (55t)^a About 350 feet (106.7 m.) above the Brigham quartzite, in the limestone of the Ute limestone [Walcott, 1908a, p. 7], on the west side of the road, 0.5 mile (0.8 km.) above the forks, Paradise Dry Canyon (locally known as East Fork), east of Paradise, Cache County, Utah.

(32p and 55e) Spence shale member of the Ute limestone, about 100 feet (30.5 m.) above the Brigham quartzite [Walcott, 1908f, p. 197], at the mouth of the first small canyon south of Wasatch Canyon; and (54q) a drift block supposed to have come from about 1,700 feet (518.2 m.) above the Brigham quartzite, a horizon correlated with the shales forming 2d of the Bloomington formation in Blacksmith Fork Canyon [Walcott, 1908f, p. 195], in Wasatch Canyon; both east of Lakeview ranch, about 5 miles (8 km.) north of Brigham, Boxelder County, Utah.

^a The species is somewhat doubtfully identified from this locality.

(15b) About 1,700 feet (518.2 m.) above the Lower Cambrian and 2,700 feet (823 m.) below the Upper Cambrian, in the shaly limestones and calcareous shales of the Wheeler formation [Walcott, 1908f, p. 181], near Swasey Spring; (3s and 8g) same horizon as 15b, in the eastern part of Wheeler Amphitheater, east of Antelope Springs; (11a) lower portion of the shales forming the Wheeler formation in Rainbow Valley; (4) *drift pieces believed to have come from the horizon of 15b, collected near Antelope Springs*; (3x) about 2,200 feet (670.6 m.) above the Lower Cambrian and 2,200 feet (670.6 m.) below the Upper Cambrian in the limestones forming 1d of the Marjum limestone [Walcott, 1908f, p. 180], 2.5 miles (4 km.) east of Antelope Springs, in ridge east of Wheeler Amphitheater; (11q, 11y, and 30g) about 2,350 feet (716.3 m.) above the Lower Cambrian and 2,050 feet (624.8 m.) below the Upper Cambrian, in the limestone forming 1c of the Marjum limestone [Walcott, 1908f, p. 180], 2.5 miles (4 km.) east of Antelope Springs, in ridge east of Wheeler Amphitheater; and (10y) about 2,900 feet (884 m.) above the Lower Cambrian and 1,500 feet (457.2 m.) below the Upper Cambrian in the central part of 1a of the Marjum limestone [Walcott, 1908f, p. 179], about 1 mile (1.6 km.) south-southwest of Marjum Pass; all in the House Range [Walcott, 1908f, Pls. XIII and XV], Millard County, Utah.

(5b and 54s) Dark blue-gray Langston limestone [Walcott, 1908f, p. 198], just above the Cambrian quartzitic sandstones, north side of Twomile Canyon, near its mouth, 2 miles (3.2 km.) southeast of Malade, Oneida County, Idaho.

(55e and 163) Spence shale member of the Ute limestone [Walcott, 1908a, p. 8], about 50 feet (15.2 m.) above the Brigham quartzite and 2,755 feet (839.7 m.) below the Upper Cambrian, in a ravine running up into Danish Flat from Mill Canyon; and (59g) limestones immediately overlying the Spence shale member of the Ute limestone [Walcott, 1908a, p. 8], in a saddle north of the creek which flows into Mill Canyon from the west; both about 5 miles (8 km.) west-southwest of Liberty and 15 miles (24.2 km.) west of Montpelier, Bear Lake County, Idaho.

(58j) About 1,900 feet (579 m.) above the Lower Cambrian, and 3,100 feet (945 m.) below the Upper Cambrian near the base of the limestone forming 2 of the Stephen formation [Walcott, 1908c, p. 238 (7)], on the east side of Mount Stephen, about 3,000 feet (914 m.) above the Canadian Pacific Railway track east of Field; and (14s) about 2,300 feet (701 m.) above the Lower Cambrian and 2,700 feet (823 m.) below the Upper Cambrian, in the *Ogygopsis* zone of the Stephen formation [Walcott, 1908f, p. 210], on the northwest slope of Mount Stephen, above Field on the Canadian Pacific Railway; both in British Columbia, Canada.

ACROTHELE SUBSIDUA HERA Walcott.

Plate LX, figure 9.

Acrothele subsidua hera WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 3, p. 87, Pl. VIII, fig. 15. (Described and discussed as below as a new species. Fig. 15 is copied in this monograph, Pl. LX, fig. 9.)

This variety is separated from *Acrothele subsidua* (White) by the more elongate outline of the ventral valve and more posterior position of the apex, the relative position of the latter being between the posterior position of the apex of *Acrothele spurri* and the more anterior position of the apex of *A. subsidua*. An obscurely defined false area begins at the apical opening and diverges toward the margin. It is marked by a slight median ridge. The exterior layers of the shell are exfoliated, carrying with them the outer portion of the apical opening. The inner portion is rather large, and from the presence of an elongate tubercle on each side it is apparent that there was a similar tubercle on the interior surface on each side of the apex a little in advance of the opening.

The surface of an interior layer is marked by fine concentric lines, numerous very fine radiating lines, and four sharp ridges that radiate from the apex to the front margin.

Observations.—This species is represented by a single specimen that occurs in the buff-weathering gray limestone interbedded in the shale carrying fragments of *Olenellus*. It is quite distinct from *A. spurri*, with which it is associated, and appears to be a progenitor of *A. subsidua*, which occurs so abundantly in the Middle Cambrian strata much higher up in the section.

FORMATION AND LOCALITY.—Lower Cambrian: (31a) Limestone and interbedded siliceous shales of the Pioche formation [Walcott, 1908a, p. 11], just above the quartzite on east side of anticline, near Pioche, Lincoln County, Nevada.

ACROTHELE SUBSIDUA LÆVIS n. var.

This variety is distinguished by the partial or complete absence of the fine granulation on the epidermal layer characteristic of *Acrothele subsidua* (White). The shells of the variety have the same general outline and form as the species, and vary in size from 3 to 7 mm. in diameter.

I do not regard this variety as having much value, as there are numerous gradations from the smooth surface to the granulated surface typical of the species.

The associated fossils indicate the central portion of the Middle Cambrian section at about the horizon of the lower portion of the Marjum limestone of the House Range section of Utah.

FORMATION AND LOCALITY.—**Middle Cambrian:** (3e) *Thin-bedded limestone less than 400 feet (121.9 m.) above the quartzitic sandstones of the Cambrian, at Ophir, Oquirrh Range, Tooele County;* and (3x) about 2,200 feet (670.6 m.) above the Lower Cambrian and 2,200 feet (670.6 m.) below the Upper Cambrian, in the limestones forming 1d of the Marjum limestone [Walcott, 1908f, p. 180], 2.5 miles (4 km.) east of Antelope Springs, in ridge east of Wheeler Amphitheater, House Range [Walcott, 1908f, Pls. XIII and XV], Millard County; both in Utah.

ACROTHELE TURNERI Walcott.

Plate LX, figures 7, 7a.

Acrothele turneri WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 3, pp. 87-88, Pl. IX, fig. 12. (Described and discussed as below as a new species. Fig. 12 is copied in this monograph, Pl. LX, fig. 7.)

General outline broad oval, ventral valve slightly conical, with the apex at about the posterior third of the length of the valve; apex short and perforated on the back side of its point by a minute pedicle opening; false area indicated by a slight flattening between the apex and posterior margin. Dorsal valve gently convex; beak marginal.

Surface marked by fine concentric lines and striæ of growth. Shell corneous and made up of a few very thin lamellæ.

The largest shell has a length of 2.5 mm.; width, 2.75 mm.

Observations.—This neat little shell differs from *Acrothele subsidua* (White) in the absence of the surface characters of that species and from *A. spurri* by the more anterior position of its beak and smooth surface. It belongs to the group of *Acrothele* represented by *A. borgholmensis*. (Compare Pl. LX, fig. 7, with Pl. LXIII, fig. 2.)

The specific name was given in honor of Mr. H. W. Turner.

FORMATION AND LOCALITY.—**Middle Cambrian:** (7r) *Calcareous shales 4 miles (6.4 km.) south-southeast of Emigrant Peak, Silver Peak quadrangle (U. S. Geol. Survey), Esmeralda County, Nevada.*

Specimens that are somewhat doubtfully referred to *Acrothele turneri* Walcott occur at the following locality:

Middle Cambrian: (54a) About 750 feet (228.6 m.) above the Brigham quartzite and 3,440 feet (1,048.5 m.) below the Upper Cambrian, in the shales forming 2a of the Ute limestone [Walcott, 1908f, p. 196], in Blacksmith Fork Canyon, about 10 miles (16.1 km.) east of Hyrum, Cache County, Utah.

ACROTHELE VILLABOIMENSIS Delgado.

Acrothele villaboimensis DELGADO, 1904, Comunicações Comissão Serviço Geol. Portugal, tome 5, fasc. 2, p. 365, Pl. IV, fig. 28. (Described and discussed in French as a new species.)

Obolella maculata DELGADO [not SALTER], 1904, idem, p. 364, Pl. IV, fig. 24. (Discussed in French.)

Delgado [1904, p. 365] states that this species is characterized by the longitudinally oval outline of the ventral valve. The photograph of the type specimen shows that the apex is a short distance from the posterior margin, and that distinct concentric lines of growth occur, also that there are three or more fine plications near the front margin. The presence of the plications appears to indicate that the specimen has been laterally compressed, and thus given a longitudinally oval outline. If this view is correct the outline of the ventral valve was probably nearly circular. It may be that Plate IV, figure 24, of "*Obolella maculata*" [Delgado, 1904, p. 364] represents the dorsal valve of this species.

The only form with which we can compare this species is *Acrothele maculata* (Salter) of the Middle Cambrian of Wales. Both species have the apex of the ventral valve far back toward the posterior margin. Distorted specimens of the ventral valve of *Acrothele maculata* have the same outline as the ventral valve of *A. villaboimensis*. It is not probable that they

are identical species; they are associated with quite different faunas and little is known of the specific details of either species.

This species derives its specific name from its occurrence near Villa Boim.

FORMATION AND LOCALITY.—Lower Cambrian: (351 [Delgado, 1904, p. 365]) Shales at Monte de Valbom, north-east of Villa Boim, Province of Alemtejo, Portugal.

ACROTHELE WOODWORTHI Walcott.

Plate LX, figure 6.

Acrothele woodworthi WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 3, p. 88, Pl. IX, fig. 11. (Described and discussed as below as a new species. Fig. 11 is copied in this monograph, Pl. LX, fig. 6.)

Ventral valve transversely and irregularly oval in outline, convex, with the apex a little back of the center of the valve; pedicle opening, as indicated by the matrix of the exterior, just back of the apex; a subtriangular, gently convex false area is obscurely outlined by lines radiating from the apex to the posterior margin; the posterior margin is arched upward one-third or more of the distance from the plane of the margin of the valve to the apex.

Surface marked by concentric growth lines with fine striæ between, and a number of low, rounded, more or less obscure, radiating ribs. The shell is relatively thick and replaced by the calcareous matter of the matrix.

Observations.—This species is based on two specimens of the ventral valve collected by Prof. J. B. Woodworth. The generic reference is not entirely satisfactory as the pedicle opening has not been clearly seen and the convex false area suggests the area of *Micromitra* (Pl. II, fig. 1) more than that of any *Acrothele* except *A. spurri* Walcott.

The specific name is given in honor of Prof. J. B. Woodworth.

FORMATION AND LOCALITY.—Lower Cambrian: (326c) "Nahant limestone," Pulpit rock, Nahant, Essex County, Massachusetts.

ACROTHELE YORKENSIS Walcott.

Plate LIX, figures 4, 4a-b.

Acrothele yorkensis WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 3, pp. 88-89, Pl. IX, fig. 10. (Described and discussed as below as a new species. Fig. 10 is copied in this monograph, Pl. LIX, fig. 4.)

This species is represented by the casts, in the fine clay shales, of the exteriors of the valves, and a few imperfect casts of the interior. The shell is large for a species of this genus. Ventral valve moderately convex, with the apex in a specimen 9 mm. long 1.5 mm. from the posterior margin. The general outline is subcircular, with the length and width approximately the same. Dorsal valve with the apex marginal. The original convexity of the valves is unknown, as all of the specimens are flattened in the shale.

Surface marked by concentric ridges and striæ of growth, and a few obscure, rounded, radiating ridges. In addition there is a fine granulation of the type of that of *A. coriacea*, the irregular, more or less inosculating, minute, rounded ridges having fine tubercles upon them.

A large ventral valve has a length and width of 11 mm. Other specimens of the same size occur, although the average size is about 8 mm. Substance of the shell is unknown.

One or two poor interiors of the ventral valve show a small visceral cavity, and rather slender main vascular sinuses that appear to originate beside the pedicle opening. The latter opens on the back slope of the apex and enlarges as it passes through the shell. The interior of the dorsal valve shows a rather strong central ridge that extends beyond the center of the shell, also a rather small cardinal scar on each side of the median ridge close to the posterior margin.

Observations.—This shell is of the general type of *Acrothele matthewi* (Hartt). It differs in its larger size, and it is not probable that a species would occur in the inner Appalachian trough which is present in the sediments near the margin of the Atlantic Basin. The fauna

associated with *A. yorkensis* is of the Middle Cambrian type of the interior trough and quite unlike that of the *Paradoxides* fauna of the Atlantic Coast Province. In size this species approaches *A. (Redlichella) granulata* (Linnarsson), but it differs from that species in its minutely granulated surface.

This species derives its specific name from its occurrence near York, Pennsylvania.

FORMATION AND LOCALITY.—Middle Cambrian: (48d) Argillaceous shales in railroad cut alongside of gas house, city of York, York County, Pennsylvania.

ACROTHELE sp. undt. a.

Plate LXIII, figure 5.

This species is represented by a single specimen of a cast of the interior. This cast shows the base of the apical opening, which is rather large, a short visceral cavity, the central portion of which was somewhat elevated, and clearly defined main vascular sinuses that originate at the sides of the base of the pedicle opening, and extend forward well toward the front of the valve, gradually diverging at the center, so as to be about one-third the distance from the median ridge to the margin; rather strong muscle scars occur beside the main vascular sinuses, where the latter curve forward into the body of the valve. Two scars, the transmedian and anterior lateral, are clearly shown. A fragment of the shell is preserved back of the cast of the pedicle opening that indicates that the shell was rather thick over the umbonal portions.

The specimen has a length of 7 mm., with the breadth the same. Nothing is known of the exterior surface. The interior shows a few obscure lines of growth and fine radiating striæ.

This species suggests the ventral valve of *Acrothele yorkensis* Walcott in form, but in the absence of an exterior or other characters for comparison, no specific designation is given to it.

FORMATION AND LOCALITY.—Lower Cambrian: (319b) Conglomeratic limestones containing *Olenellus?*, St. Simon, Province of Quebec, Canada.

ACROTHELE sp. undt. Moberg.

Acrothele MOBERG, 1892, Geol. Fören. i Stockholm Förhandl. for 1902, Bd. 14, Hft. 2, pp. 114–115, Pl. III, fig. 9. (Described in Swedish; see below for translation.)

Moberg describes the species as follows:

Of this genus, none but exfoliated specimens have been met with. They do not appear to show characters sufficient for specific determination. The shell has an almost circular circumference, with the back edge, along a distance constituting about one-fifth of the whole circumference, somewhat truncated. From the apex, which is situated near the posterior margin, the shell slopes pretty evenly both toward the anterior and the posterior margins, so that these two parts form approximately a right angle with each other at the apex. Traces of concentric lines of growth are visible.

In the position of the apex and the convexity of the ventral valve the cast of this shell is much like that of the forms from the Lower Cambrian of Bic, Canada (Pl. LXIII, fig. 5).

FORMATION AND LOCALITY.—Lower Cambrian: (310e) Sandstone boulder on the beach between Ekerum and Stora Rör; (310f) sandstone boulders west of Ekerum; and (310g) sandstone boulders south of Stora Rör; all [Moberg, 1892b, p. 115] on Oeland Island, Sweden.

REDLICHELLA Walcott, ^a subgenus of ACROTHELE.

Acrothele (Redlichella) WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 3, pp. 89–90. (Described and discussed as below as a new subgenus.)

Acrothele (Redlichella) WALCOTT, 1908, idem, vol. 53, No. 4, pp. 142 and 146, and Pl. XI. (Classification of subgenus.)

This subgenus of *Acrothele* has all the external characters of the type species of *Acrothele*, *A. coriacea* Linnarsson. It differs in the interior markings of the valves. The visceral area

^a The synonymy for this subgenus does not give a complete record of the various genera under which the species now included in *Redlichella* were formerly placed. It gives only those references in which the genus is discussed or described. To complete the record the following mere generic references are listed:

Acrothele Linnarsson [1876, p. 24].
Acrothele Swanston [1877, Pl. VII, figs. 29a–c].
Acrothele Linnarsson [1877, p. 373].
Acrothele Davidson [1883, p. 214].

Acrothele Walcott [1886b, p. 109].
Acrothele Swanston [1886, Pl. VII, figs. 20a–c].
Acrothele Hall and Clarke [1892c, p. 100].

of the ventral valve is large and clearly defined, as in *Botsfordia granulata* (Redlich), and the main vascular sinuses are very strong and close to the pedicle aperture, as in the latter species. In the interior of the dorsal valve the cardinal scars are very large and extend forward nearly one-third the length of the valve.

Type.—*Acrothele granulata* Linnarsson.

I was at first inclined to place this form under *Botsfordia*, but the advanced position of the apex and pedicle opening of the ventral valve indicates a closer affiliation with *Acrothele*. The short listrium of *Botsfordia* has developed in *Redlichella* to the strong false area of *Acrothele*, but the visceral area and main vascular sinuses of *Botsfordia* remain practically unchanged. I regard *Redlichella* as a form intermediate in development between *Botsfordia* and *Acrothele*.

The subgeneric name is given for Dr. Karl A. Redlich, of the Geological Survey of India.

- Acrothele granulata* Linnarsson, HALL and CLARKE, 1892, Nat. Hist. New York, Paleontology, vol. 8, pt. 1, pp. 100-101. (Discussed.)

The shell of *Acrothele (Redlichella) granulata* resembles so closely that of *Acrothele coriacea* Linnarsson (p. 642) that I will only call attention to the points of difference between them.

On the average, *A. (R.) granulata* is a longer, stronger shell; its surface is more coarsely granular, the pedicle aperture is much larger, and the tubercles in front of it much smaller. The false area is usually less distinct, but it is sometimes distinct and has a longitudinal median line; the posterior margin arches up at the false area, and the dorsal valve arches up so as to fit closely against the curved margin; the interior of the ventral valve of *A. (R.) granulata* has a visceral area that is obtusely pointed in front and on each side extends out to the main vascular sinuses, which originate nearer the pedicle opening than in *A. coriacea*. The main vascular sinuses of *A. (R.) granulata* are much nearer the median line than those of *A. coriacea*. The difference in the visceral area and vascular sinuses was found in specimens from the *Paradoxides forchhammeri* beds of Gudhem, and also the *P. ælandicus* zone of Bornholm.

In the dorsal valve of *A. (R.) granulata* the cardinal scars are longer and nearer the median ridge.

A large ventral valve has a length of 9 mm.; width, 10.5 mm. A large dorsal valve has a length of 10 mm.; width, 12 mm.

Acrothele (Redlichella) granulata is a form intermediate between the typical *Acrothele coriacea* Linnarsson and *Botsfordia granulata* (Redlich). It has the exterior appearance of *Acrothele coriacea*, and the apex of the ventral valve is well in advance of the posterior margin, but the interior of the ventral valve has the strongly marked visceral area of *Botsfordia granulata*, and strong vascular sinuses that are close to the pedicle opening.

FORMATION AND LOCALITY.—Middle Cambrian: (8z) Limestones of *Paradoxides ælandicus* zone at Borgholm, Oeland Island; (309f) shale at Borgholm, Oeland Island; (310o) limestone of the *Paradoxides tessini* zone at Borgholm, Oeland Island; (320s [Linnarsson, 1877, p. 374]) at St. Frö, Oeland Island; (320b) limestones forming 2d of the *Paradoxides* zone, the *Agnostus lœvigatus* horizon, at Gudhem, 12.5 miles (20.1 km.) south-southeast of Skara, Province of Skaraborg; (3201 [Linnarsson, 1876, p. 24]) drift blocks supposed to have come from the *Paradoxides ælandicus* zone [Linnarsson, 1876, p. 6], at Lillviken, near Oestersund, Province of Jemtland; and (320t [Linnarsson, 1876, p. 24]) on Billstaån River, parish of Hackås, Province of Jemtland; all in Sweden.

Genus *DISCINOLEPIS* Waagen.

[ὀστρακός, quoit; and λείρις, scale.]

- Discinolepis* WAAGEN, 1885, Mem. Geol. Survey India, Paleontologia Indica, 13th ser., Salt Range Fossils, vol. 1, pt. 4, fas. 5, pp. 749-750. (Described and discussed as a new genus, part of the next to the last paragraph being copied below.)
- Discinolepis* Waagen, HALL and CLARKE, 1892, Eleventh Ann. Rept. State Geologist New York for 1891, p. 247. (Described.)
- Discinolepis* Waagen, HALL and CLARKE, 1892, Forty-fifth Ann. Rept. New York State Museum for 1891, p. 563. (Copy of preceding reference.)
- Discinolepis* Waagen, HALL and CLARKE, 1892, Nat. Hist. New York, Paleontology, vol. 8, pt. 1, p. 90. (Original description, Waagen, 1885, p. 749, copied.)
- Discinolepis* Waagen, WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 4, Pl. XI, and pp. 142 and 146. (Classification of genus.)

As this genus is based on one species, the description of the latter will give all that is known of the genus. Waagen [1885, p. 749] states that this genus differs from all described genera of the Discinidæ:

From *Discina*, *Discinisca*, and *Orbiculoides* it differs in having an incision and not a slitlike foramen in its lower valve for the passage of a peduncle. In *Trematis* a similar incision or emargination seems sometimes to occur, but the sculpture of the valves is quite different from that appearing in *Discinolepis*. *Schizocerania* has an incision, but it is much larger than in the Indian form.

Type.—*Discinolepis granulata* Waagen.

DISCINOLEPIS GRANULATA Waagen.

Plate LXXXI, figures 3, 3a-b.

- Discinolepis granulata* WAAGEN, 1885, Mem. Geol. Survey India, Paleontologia Indica, 13th ser., Salt Range Fossils, vol. 1, pt. 4, fas. 5, pp. 750-751, Pl. LXXXVI, figs. 5, 6, and 7. (Described and discussed as a new species. The specimen represented by fig. 6 is redrawn in this monograph, Pl. LXXXI, fig. 3; the specimen represented by fig. 5 is redrawn (in different positions) in this monograph, Pl. LXXXI, figs. 3a and 3b.)
- Discinolepis granulata* WAAGEN, 1891, idem, vol. 4, pt. 2, Pl. II, figs. 15 and 16. (No text reference. Figs. 15 and 16 are drawn from the specimens represented in the preceding reference, Pl. LXXXVI, figs. 5 and 6, respectively.)
- Discinolepis granulata* Waagen, HALL and CLARKE, 1892, Eleventh Ann. Rept. State Geologist New York for 1891, p. 247, figs. 256 and 257. (No text reference. Figs. 256 and 257 are copied from Waagen, 1885, Pl. LXXXVI, figs. 5b and 7, respectively.)
- Discinolepis granulata* Waagen, HALL and CLARKE, 1892, Forty-fifth Ann. Rept. New York State Museum for 1891, p. 563, figs. 256 and 257. (Copy of preceding reference.)
- Discinolepis granulata* Waagen, HALL and CLARKE, 1892, Nat. Hist. New York, Paleontology, vol. 8, pt. 1, p. 90, figs. 45 and 46. (No text reference. Figs. 45 and 46 are copied from Waagen, 1885, Pl. LXXXVI, figs. 5b and 7, respectively.)

Shell transversely broad oval. Ventral valve nearly flat except at the umbo and apex. Apex a little in front of the posterior margin and about three-fourths of a millimeter high; it is divided by a median depressed line which gives a slightly elevated semicircular node on each side. From the depressed median line a narrow, elongate, triangular opening extends to the margin of the valve; this opening has the position and form of the false deltidium of some species of *Acrotreta*, but there is no outline of an area. The lines and striæ of growth arch around and terminate at the edges of the opening.

Surface of the shell marked by fine concentric lines of growth and fine papillæ which are outlined by oblique lines curving from each side of the shell forward and then outward to the opposite side from which they originate. It is the same type of surface as that on *Micromitra* (*Iphidella*) *pannula* (White) (Pl. IV). Where the surface is slightly worn the papillæ appear like fine granules.

The substance of the shell appears to be calcareoconeous and the shell to be made up of several thin lamellæ. The two ventral valves are 5 mm. in width and 4 and 5 mm. in length, respectively.

These measurements differ from Waagen's, but as the shells are imperfectly preserved at margins the size assumed is a matter of personal judgment.

Waagen [1885, p. 750] describes the dorsal valve from specimens on a slab of sandy shale that are more or less crushed. The surface of these shells is marked only by very fine concentric striæ and two show an opening beneath the apex similar to that of the ventral valve of *Discinolepis granulata*. I do not find in the material any clearly defined dorsal valve with the papillose surface. The material representing the concentrically striated species is too poorly preserved to warrant the description of a second species. I do not know of any related species.

I am indebted to the director of the Geological Survey of India, Dr. T. H. Holland, for the opportunity to study and illustrate the type material of this genus and species.

FORMATION AND LOCALITY.—**Middle Cambrian**: Lower portion of the "Neobolus beds" of the Khussak group, in purplish-colored, fine-grained, micaceous sandstone at the following localities [Waagen, 1885, p. 751]; (357a) at *Jutana*; and (357c) near the fresh-water springs in the gorge above the salt mines at Kiura (Khwera); both in the Salt Range, India.

Subfamily ACROTRETINÆ Walcott and Schuchert.

Genus LINNARSSONELLA Walcott.^a

Linnarssonella WALCOTT, 1902, Proc. U. S. Nat. Mus., vol. 25, pp. 601-602. (Described and discussed as below as a new genus.)

Linnarssonella WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 4, Pl. XI, and pp. 142 and 146. (Classification of genus.)

Ventral valve convex with a slightly incurved beak projecting over a low false area. Pedicle opening at the apex of the beak. A very slight trace of a pseudodeltidium occurs beneath the beak, dividing the false area midway, as in the genus *Micromitra*; the false area arches slightly upward and backward in some specimens, while in others of the same species its edge is nearly coincident with the plane of the edge of the shell. The true cardinal area is well defined and strongly marked by a shallow pedicle furrow (Pl. LXXVIII, figs. 8e and 9b). The dorsal valve is slightly convex, with a minute beak at the posterior margin. Surface marked by very fine concentric striæ and undulations of growth. Shell strong, thick, and built up of a thin outer layer and numerous inner layers or lamellæ that are arranged more or less obliquely to the outer layer. All the known species are small, not exceeding 2.5 mm. in diameter.

The cast of the interior of the ventral valve shows the presence of two well-marked cardinal scars, one on each side of the main vascular canals well toward the posterior border of the valves. The main vascular canals of the ventral valve were large, extending nearly to the frontal margin, and including between them back of the center of the valve a small visceral area. The cast of the pedicle opening occurs just in front of the union of the main vascular sinuses. The cast of the interior of the dorsal valve (Pl. LXXIX, fig. 11) shows two large cardinal scars; two central scars (h); and traces of a minute anterolateral scar (j); strong vascular canals; a well-defined area and pedicle furrow; and a narrow median ridge extending in some shells to the anterior third of the valve.

Type.—*Linnarssonella girtyi* Walcott; second species, *L. minuta* (Hall and Whitfield); third species, *L. tennesseensis* Walcott.

This is a most interesting type, combining characters of *Micromitra* and *Acrotreta*. *Bicia*, of the *Olenellus* fauna, has a strikingly similar dorsal valve, and the ventral valve is not unlike if the narrow pedicle furrow of *Bicia* is closed so as to provide a pedicle aperture.

Linnarssonella girtyi occurs in great abundance in a single layer in the Middle Cambrian of the Black Hills, North Dakota; also at two localities at the same relative stratigraphic horizon in Oklahoma and at several localities in the Middle Cambrian limestones of Missouri.

^a The synonymy for this genus does not give a complete record of the various genera under which the species now included in *Linnarssonella* were formerly placed; it gives only those references in which the genus is discussed or described. To complete the record the following mere generic references are listed:

Lingulepis? Hall and Whitfield [1877, p. 206].
Lingulepis? Walcott [1884b, p. 13].
Obolella? Walcott [1897a, p. 404].
Lingulella Schuchert [1897, p. 257].

Obolella Walcott [1899, p. 443].
Acrotreta Walcott [1901, p. 673].
Meekina Walcott [1905a, p. 313].

The Missouri specimens were at first thought to be a distinct species, to which the name *L. broadheadi* was given, but the description was not published. By oversight the name *L. broadheadi* was published [Walcott, 1902, p. 601] in the preliminary notes on the genus. The valves of *L. minuta* almost cover a fragment of sandy shale from the Eureka district, Nevada. *Linnarssonella tennesseensis* is fairly abundant in sandy shales and thin-bedded sandstones, also in argillaceous shales above the sandstone of the Rome formation. Three species occur in the Upper Cambrian of the House Range section of western Utah. The lowest in the section is *L. transversa*; about 200 feet higher in the section, *L. modesta*; and a short distance above, *L. nitens*. These species occur in abundance in the bluish-gray limestones. *Linnarssonella urania* is moderately abundant in the Middle Cambrian, compact, dove-colored limestones of the Wasatch Range.

Failing to establish a satisfactory genus in honor of Linnarsson in the first instance,^a I make another attempt with this rare and interesting form.

LINNARSSONELLA GIRTYI Walcott.

Plate LXXVIII, figures 5, 5a; Plate LXXIX, figures 1, 1a-r.

Linnarssonella broadheadi WALCOTT, 1902, Proc. U. S. Nat. Mus., vol. 25, p. 601. (Name referred to but not defined or described.^b)

Linnarssonella girtyi WALCOTT, 1902, idem, pp. 602-603. (Described and discussed as below as a new species.)

Shell minute. General form broad ovate to subcircular. Ventral valve convex; beak small and slightly incurved over the false area; false area short and varying from vertical to a backward inclination of 45° to 50° with the plane of the edge of the valve; in some examples the margin of the false area arches (Pl. LXXIX, fig. 1a') but in others it appears to be straight (fig. 1b). A very slightly indicated pseudodeltidium occurs beneath the beak that gradually widens to the margin, very much as in *Micromitra pealei*. Pedicle opening minute exteriorly, but the tube increases in size toward the inner surface of the shell. In one very perfect shell the aperture appears to open into a narrow elongate depression just in front of the beak, but it usually is seen as a minute, circular perforation at the apex of the beak. Dorsal valve gently convex, with a minute beak at the posterior margin. Surface of the shell glossy and smooth to the unaided eye, but a strong magnifier shows very fine concentric striæ and lines of growth; the inner surface is marked outside of the visceral area by very fine radiating striæ. The shell is formed of several layers or lamellæ, and, judging from the depth of the impressions of the muscle scars and vascular markings, rather thick over the central and posterior portions. The average length of the ventral valve is 1.5 to 1.75 mm.; the dorsal valve is slightly shorter.

The cast of the interior of the ventral valve shows the presence of a large cardinal scar on each side of the visceral area, and outside of the very strong vascular canal; they are oval in outline and probably the point of attachment of a strong muscle or muscles; their variation in size and position is shown by Plate LXXIX, figures 1k and 1m-p. The visceral area is small, but is well defined in Plate LXXIX, figures 1n, 1o, and 1p. Of the vascular canals only the main trunks are shown by strong ridges in the casts, their form and extension being finely exhibited by figures 1m to 1p; in figure 1k they extend almost in a direct line from the beak to the anterolateral margins of the valve. The cast of the interior of the pedicle tube is usually broken off; its position is shown in Plate LXXIX, figure 1n. The interior of the dorsal valve is beautifully shown by figure 1l; the strong cardinal area with its well-defined pseudodeltidium, the large oval cardinal scars immediately in front of the area, and the strong vascular canals are as clearly defined as in the large shells of *Obolus*. The cardinal scars are divided into three parts by two transverse lines crossing the outer slope more or less obliquely, but the divisions on the two sides are unequal; the inner slopes of the scars are finely polished and afford no evidence of the attachment of muscles. Traces of the central scars occur on the outer slope

^a *Linnarssonella* [Walcott, 1885, p. 115], now referred to *Acrotreta*.

^b Under the impression that the forms were distinct this name was given to them, and the name was overlooked when the description of the genus was published [Walcott, 1902, p. 601].

of the east of a rather strong median ridge; they are elongate oval in outline, the major axis inclining posteriorly toward the median ridge. What may be the impression of an antero-lateral scar occurs on the median ridge a little in advance of the central scars.

Observations.—*Linnarssonella girtyi* differs from *L. minuta* (Hall and Whitfield) in the greater convexity of the ventral valve and the median ridge of the dorsal valve. The Oklahoma specimens show a longer false area (Pl. LXXIX, fig. 1q'') on some shells but on others it is much like that of *L. girtyi* from the Black Hills.

The specific name is given in recognition of the paleontologic work of Dr. George H. Girty.

FORMATION AND LOCALITY.—**Upper Cambrian:** (369) Sandstone in the Elvins formation in the eastern limits of the town of Flat River, St. Francois County, Missouri.

(9q) About 10 feet (3 m.) above the porphyry contact and 90 feet (27.4 m.) below the Arbuckle limestone, in limestone of the Reagan sandstone, in middle of W. $\frac{1}{2}$ sec. 2, T. 4 N., R. 13 W.; (9r) about 45 feet (14 m.) above the porphyry contact in the limestone of the Reagan sandstone, in SE. $\frac{1}{4}$ NE. $\frac{1}{4}$ sec. 2, T. 4 N., R. 13 W.; and (9p) about 160 feet (48.8 m.) above the porphyry contact in the limestone of the Reagan sandstone, in SE. $\frac{1}{4}$ NE. $\frac{1}{4}$ sec. 2, T. 4 N., R. 13 W.; all about 15 miles (24.2 km.) northwest of Fort Sill, Comanche County, Oklahoma.

(9v) Limestone of the Reagan sandstone, about 250 feet (76 m.) below the Arbuckle limestone, SW. $\frac{1}{4}$ sec. 17, T. 4 N., R. 12 W., about 11 miles (17.7 km.) northwest of Fort Sill, Comanche County, Oklahoma.

(12p) About 225 feet (69 m.) above the igneous rocks in the limestone of the Reagan sandstone at the northwest extremity of the Arbuckle Mountains, about 4 miles (6.4 km.) east of Homer, Carter County, Oklahoma.

(14i) Limestone 1 mile (1.6 km.) west of Cherokee, San Saba County, Texas.

(32t) Limestone about 3,650 feet (1,112.5 m.) above the Cambrian quartzitic sandstones, in Fandango Spring canyon on the east side of the Dugway Range, about 5 miles (8 km.) north of where the stage road between Vernon and Deep Creek crosses the divide, Tooele County, Utah.

Middle Cambrian: (88a) Limestone about 100 feet (30.5 m.) above the quartzitic sandstone at the base of the Cambrian, in the northern suburbs of Deadwood; (165) limestone on the east side of the valley in railroad cut about 1 mile (1.6 km.) below the main part of Deadwood; and (17k) limestone thrown out on the dump of the Great Northern shaft, southeast of Twobit; all in the Black Hills, South Dakota.

(11k) Limestones of the "Edgewise beds," beneath the Elvins formation, St. Francois County; and (11e) thin-bedded limestone south-southwest of Potosi, Washington County; both in Missouri.

(313e) Limestone 2 miles (3.2 km.) west of Green's ranch, White Pine County, Nevada.

A shell that is somewhat doubtfully referred to this species occurs at the following locality:

Upper Cambrian: (9q) About 10 feet (3 m.) above the porphyry contact and 90 feet (27.4 m.) below the Arbuckle limestone, in limestone of the Reagan sandstone, in middle of W. $\frac{1}{2}$ sec. 2, T. 4 N., R. 13 W., about 15 miles (24.2 km.) northwest of Fort Sill, Comanche County, Oklahoma.

LINNARSSONELLA MINUTA (Hall and Whitfield).

Plate LXXIX, figures 2, 2a-b.

Lingulepis? minuta HALL and WHITFIELD, 1877, U. S. Geol. Expl. 40th Par., vol. 4, pt. 2, pp. 206-207, Pl. I, figs. 3 and 4. (Described and discussed as a new species. The specimens represented by Pl. LXXIX, figs. 2, 2a-b, occur on the same hand specimen of sandy shale as the specimens figured by Hall and Whitfield, but they are not the same specimens.)

Lingulepis? minuta Hall and Whitfield, WALCOTT (in part), 1884, Mon. U. S. Geol. Survey, vol. 8, p. 13. (Localities and range mentioned, see p. 668.)

Obolella? minuta (Hall and Whitfield), WALCOTT, 1897, Am. Jour. Sci., 4th ser., vol. 3, p. 404. (Merely changes generic reference.)

Lingulella minuta (Hall and Whitfield), SCHUCHERT, 1897, Bull. U. S. Geol. Survey No. 87, p. 257. (Merely changes generic reference.)

Obolella minuta (Hall and Whitfield), WALCOTT, 1899, Mon. U. S. Geol. Survey, vol. 32, pt. 2, p. 443. (Merely changes generic reference.)

Acrotreta minuta (Hall and Whitfield), WALCOTT, 1901, Proc. U. S. Nat. Mus., vol. 23, p. 673. (Merely changes generic reference.)

Linnarssonella minuta (Hall and Whitfield), WALCOTT, 1902, idem, vol. 25, pp. 603-604. (Described and discussed as below.)

Shell small; general form broad ovate, with the ventral valve slightly subacuminate. The convexity of the two valves is nearly the same and in each the minute beak appears to be at the posterior margin. The false area of the ventral valve is small and divided midway by a faint, narrow pseudodeltidium; it is on the plane of the margin of the valve. Pedicle

opening minute, elongate, and situated on the slope just in front of the beak. Dorsal valve a trifle less convex than the ventral.

The outer surface of the shell is marked by fine concentric striæ and lines of growth, and the inner lamellæ and inner surface are marked by fine radiating striæ. The shell is formed of several thin layers or lamellæ, those of the anterior and lateral portions being more or less oblique to the outer surface layer; the shell is also thickened in the visceral region by irregular additions on the inside. The average length of the ventral valve is 2 to 2.5 mm.; the dorsal is a little shorter. The interior of the ventral valve shows a cardinal scar on each side well out toward the lateral margin, which corresponds to the position of the transmedian and anterolateral scars in *Obolus apollinīs*. The visceral area is small and compressed between the sinuses occupied by the large, main vascular canals. The inner opening of the pedicle tube is oval and situated at the posterior portion of the visceral depression at the margin of the area. The main vascular canals start near the beak and gradually diverge toward the anterolateral margins of the valve. The interiors of the dorsal valve associated with the two ventral valves illustrated are all so imperfect that only a median ridge like that in *Acrotreta* can be clearly determined; this ridge varies greatly in size and length in different specimens.

Observations.—In a hasty examination of this species [1884b, p. 13] I confused the dorsal valve with that of *Acrotreta* and considered the ventral valve as the type, placing it under *Lingulepis*, stating that it had nearly the same vertical range and geographic distribution as *Obolus mæra*. As now known it is confined to the following localities, one of the two being the locality discovered by the geologists of the Fortieth Parallel Survey.

The generic reference is somewhat doubtful on account of our limited knowledge of the interior of the dorsal valve and the position of the area of the ventral valve.

FORMATION AND LOCALITY.—Ordovician: (313k) Limestone in the White Pine district, Nye County, Nevada.

Upper Cambrian: (313h) Sandy shale on Hamburg Ridge, Eureka district [Hague, 1892, Atlas], Eureka County, Nevada.

LINNARSSONELLA MODESTA Walcott.

Plate LXXVIII, figures 8, 8a-f.

Linnarssonella modesta WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 3, pp. 90-91, Pl. IX, figs. 8 and 8a. (Described and discussed as below as a new species. Figs. 8 and 8a are copied in this monograph, Pl. LXXVIII, figs. 8 and 8e, respectively.)

Shell minute; general form subcircular. Ventral valve moderately convex; beak small and slightly incurved over a very low false area; pedicle opening minute exteriorly, with a slightly elevated, sharp ridge on each side a little in advance of the point of the beak; seen from the back, the minute aperture points backward from the bottom of a pit between the two short, sharp ridges; in a specimen from a layer of limestone a short distance above in the section, the aperture is at the point of a small nipple-like projection, apparently formed by the union of the ends of the ridges already described on each side of the aperture. Dorsal valve slightly convex, with a minute beak at the posterior margin.

Surface dull when the outer layer of the shell is preserved; it is marked by a few very fine, concentric lines of growth. The inner surface is marked by concentric lines and a few fine radiating lines. The shell is formed of several layers or lamellæ and is relatively thin.

The average diameter of the adult shell is from 1.75 to 2.25 mm.; the dorsal valve slightly shorter than the ventral.

The cast of the interior of the ventral valve shows a slight, longitudinal, median elevation and two short, not very strongly marked main vascular sinuses; several specimens indicate a slight cavity just beneath the aperture, which probably represents the inner side of the pedicle tube. The interior of a dorsal valve shows main vascular sinuses quite close to the outer margin; also two small, rounded median depressions a short distance in front of the posterior margin.

Observations.—This shell occurs in great abundance on the surface of shaly, gray limestone, about midway of the strata referred to the Upper Cambrian in the House Range

section. It differs from *L. nitens*, which occurs a short distance above it in the section, and with which it is also associated, in having a less elevated ventral valve and a less convex dorsal valve; and from *L. transversa* in being more rounded in outline and less convex. It appears to be more nearly related in form to *L. minuta* (Hall and Whitfield); it differs, however, materially in the character of the interior markings of the ventral valve, features which also separate it from *L. girtyi* Walcott and *L. tennesseensis* Walcott.

FORMATION AND LOCALITY.—**Upper Cambrian:** (30k) 1,150 feet (350.5 m.) above the Middle Cambrian and 2,175 feet (662.9 m.) below the top of the Upper Cambrian, at the top of the arenaceous shales and limestones forming 1e of the Orr formation [Walcott, 1908f, p. 176]; and (31t) about 1,175 feet (358.1 m.) above the Middle Cambrian and 2,150 feet (655.3 m.) below the top of the Upper Cambrian, in the limestone forming 1d of the Orr formation [Walcott, 1908f, p. 176]; both on Orr Ridge, about 5 miles (8 km.) south of Marjum Pass, House Range [Walcott, 1908f, Pl. XIII], Millard County, Utah.

LINNARSSONELLA NITENS Walcott.

Plate LXXVIII, figures 7, 7a.

Linnarssonella nitens WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 3, p. 91, Pl. IX, fig. 7. (Discussed as below as a new species. Fig. 7 is copied in this monograph, Pl. LXXVIII, fig. 7.)

The outline of the valves and the exterior appearance of this shell are much like those of *L. modesta*. It differs in having on the ventral valve a low, distinct area, with the perforated apex directed backward on nearly the same plane as the umbo, or most elevated portion of the valve. The dorsal valve is more convex and its interior has a strong median ridge extending forward from the posterior margin about two-thirds of the distance to the front margin, a feature but little developed in *L. modesta*. From *L. minuta* (Hall and Whitfield) it differs in the higher apex of the ventral valve, and from *L. transversa* in the latter character and in the more circular outline of the aperture of the valves.

A single specimen of *L. modesta* was found associated with this species.

In size *L. nitens* varies from 1.5 to 2 mm. in diameter.

FORMATION AND LOCALITY.—**Upper Cambrian:** (31t) About 1,175 feet (358.1 m.) above the Middle Cambrian and 2,150 feet (655.3 m.) below the top of the Upper Cambrian, in the limestone forming 1d of the Orr formation [Walcott, 1908f, p. 176], on Orr Ridge, about 5 miles (8 km.) south of Marjum Pass, House Range [Walcott, 1908f, Pl. XIII], Millard County; and (32g) about 2,575 feet (784.9 m.) above the Cambrian quartzitic sandstones, in a blue limestone about 2 miles (3.2 km.) southeast of Muskrat Spring, on the northwest face of Grautsville Peak, Stansbury Range, Tooele County; both in Utah.

LINNARSSONELLA TENNESSEENSIS Walcott.

Plate LXXIX, figures 3, 3a-k.

Linnarssonella tennesseensis WALCOTT, 1902, Proc. U. S. Nat. Mus., vol. 25, pp. 604-605. (Described and discussed as below as a new species.)

Meekina prima WALCOTT, 1905, idem, vol. 28, p. 313. (Name referred to, but it was not defined or used elsewhere.^a)

General form of ventral valve rounded subtriangular, moderately convex, with the beak curving gently over a very low false area nearly to the posterior margin. Pedicle opening minute and situated a little in front of the beak.

Surface of shell marked by fine concentric striæ and lines of growth. The interior surface shows a few fine, radiating striæ. Shell rather thick and built up of several thin layers or lamellæ.

The cast of the interior of the ventral valve shows small cardinal scars and a minute pedicle tube directed backward, very much as in *Obolella atlantica* Walcott (Pl. LV, figs. 1f-h). The area is short, narrow, and divided by a deep, narrow pedicle furrow; on each side of the latter the area projects into the valve so as to form a shelf, with a thickening at the interior angle next to the pedicle furrow; the central visceral area is confined mainly to the deep median groove; an elevated area about the anterior end of the groove probably served as the point of attachment of the central muscle; the main vascular sinuses are very strong and project well toward the front part of the valve; the composite cardinal muscle scars, which served

^a A shell is referred to as *Meekina prima*, but before the generic or specific description was published I found that the specimens were casts of the interior of *Linnarssonella tennesseensis*.

as the point of attachment of the transmedian and anterior laterals, are situated close to the posterior lateral margin of the valve.

The dorsal valve has a very short and narrow area, with a small but distinct slightly concave shelf-like projection in front of it; on each side near the posterior lateral margins a strongly defined cardinal posterior muscle scar occurs that served as the point of attachment of the transmedian, outside lateral, and middle lateral muscles. The central scars are a little in advance of the center of the valve. None of the specimens show the main vascular canals except at their base. The shells average about 3 mm. in diameter.

Observations.—The material representing this species occurs as casts of the interior and exterior surfaces, in a fine argillaceous shale. It is owing to the removal of the shell substance by solution that the cast of the area and area-like shelf of the dorsal valve is so clearly shown, also the posterior muscle scars, visceral area, etc., of the ventral valve.

The shell has the general outline of *Linnarssonella girtyi* Walcott; but it differs in having the ventral valve more acuminate, less convex, and in the apex curving over nearly to the posterior margin. It has the outline of *L. minuta* (Hall and Whitfield), but not the strong vascular sinuses and small cardinal scars of the ventral valve of that species.

The perforate ventral valve and large cardinal muscle scars relate this species to *Linnarssonella*. The composite cardinal muscle scars, area, and projection of the inner angles of the area into the area of the ventral valve, and also the interior of the dorsal valve, suggest *Dicelolomus*. The spondylium-like shelf of the dorsal valve, indicated in the cast, may be only the cast of the area projecting out into the valve (Pl. LXXIX, fig. 1r, of *Linnarssonella girtyi*). The cardinal scars and shelf-like areas of the valve separate this species from *Obolella*.

FORMATION AND LOCALITY.—Upper Cambrian: (31t) About 1,175 feet (358.1 m.) above the Middle Cambrian and 2,150 feet (655.3 m.) below the top of the Upper Cambrian, in the limestone forming 1d of the Orr formation [Walcott, 1908f, p. 176], on Orr Ridge, about 5 miles (8 km.) south of Marjum Pass, House Range [Walcott, 1908f, Pl. XIII], Millard County, Utah.

Middle Cambrian: (13) Sandstones of the Rome formation, 1.5 miles (2.4 km.) east of Post Oak Springs [Hayes, 1894, areal geology sheet], Roane County; (107b) shales in railroad cut in Bull Run, northwest of Copper Ridge [Keith, 1896b, areal geology sheet], 11 miles (17.6 km.) northwest of Knoxville, Knox County; and (12) sandy shale on Webbs Ridge in gap west of Simpson's farm, 6 miles (9.6 km.) northeast of Knoxville, Knox County; all in Tennessee.

LINNARSSONELLA TRANSVERSA Walcott.

Plate LXXVIII, figures 6, 6a-c.

Linnarssonella transversa WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 3, p. 92, Pl. IX, fig. 6. (Discussed as below as a new species. Fig. 6 is copied in this monograph, Pl. LXXVIII, fig. 6.)

This is a small shell that at first sight suggests *L. modesta*; it differs from that species in the valves being more convex, transverse instead of circular, and in having stronger concentric striæ, and, in some instances, radiating striæ. A few fragments of the interior of the dorsal valve indicate that the main vascular sinuses are well out toward the outer margin, and that small circular depressions occur on each side of the median line, very much as in the dorsal valve of *L. girtyi* Walcott (Pl. LXXIX, fig. 1r), and that two small central muscle scars are midway between the posterior and anterior margins of the valve. The average shell has a width of 2 mm., with a length of from 1.5 to 1.75 mm.

L. transversa differs by its transverse outline from all other known species of the genus.

FORMATION AND LOCALITY.—Upper Cambrian: (30j) About 950 feet (289.6 m.) above the Middle Cambrian and 2,450 feet (746.8 m.) below the top of the Upper Cambrian, near the base of the arenaceous shales and limestone forming 1e of the Orr formation [Walcott, 1908f, p. 176], on Orr Ridge, about 5 miles (8 km.) south of Marjum Pass, House Range [Walcott, 1908f, Pl. XIII], Millard County, Utah.

LINNARSSONELLA URANIA Walcott.

Plate LXXVIII, figures 9, 9a-c.

Linnarssonella urania WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 3, pp. 92-93, Pl. IX, figs. 9 and 9a. (Described and discussed as below as a new species. Figs. 9 and 9a are copied in this monograph, Pl. LXXVIII, figs. 9a and 9c, respectively.)

Shell minute, general form elongate oval. Ventral valve convex; apex minute and curved down nearly to the plane of the margin of the valve; false area, if present, must be very narrow.

Pedicle opening situated on the umbo a short distance above the point of the beak; on some shells it opens on the plane of the surface of the valve, and on others it has a rounded, slightly elevated margin. Dorsal valve slightly convex, with a minute beak at the posterior margin. Surface of the shell glossy, with very fine concentric striæ and lines of growth. A ventral valve 2.5 mm. in length has a width of 1.75 mm. The dorsal valves are somewhat shorter in proportion to the width.

A partial cast of the interior of the ventral valve shows a small visceral area in front of the pedicle opening. The interior of the dorsal valve is marked by a strong central ridge that extends from the beak four-fifths of the distance to the front margin; on each side of the median ridge, near the posterior margin, there is a rather large, clearly defined cardinal muscle scar.

Observations.—This species differs from *L. girtyi* Walcott in not having a false area in the ventral valve, and also in the position of the pedicle opening. The incurved apex is more like *L. modesta*, but the form of the ventral valve and the position of the pedicle aperture are quite different.

FORMATION AND LOCALITY.—Middle Cambrian: (55u) Limestones about 200 feet (61 m.) above the Lower Cambrian [see Walcott, 1908f, p. 171], 0.25 mile (0.4 km.) below the Maxfield mine, in Big Cottonwood Canyon, on the west front of the Wasatch Mountains, southeast of Salt Lake City, Salt Lake County, Utah.

Genus ACROTRETA Kutorga.^a

[ἄκρον, at the top; and τρυπέ, bored through.]

Acrotreta KUTORGA, 1848, Verhandl. Russ.-kais. min. Gesell. St. Petersburg for 1847, No. 12, pp. 259 and 260 (notes on genus), and p. 275 (described in German as a new genus; see p. 672 for translation).

Acrotreta Kutorga, MORRIS, 1849, Annals and Mag. Nat. Hist., 2d ser., vol. 4, pp. 316 and 318. (Characterized and discussed.)

(Described, but the only species referred to the genus ("*L. pretiosa*") is not figured and it is impossible to tell whether the authors are discussing the *Linnarssonsonia pretiosa* that has been referred to the genus *Acrotreta* (*Acrotreta sagittalis*), or to the genus *Acrothele* (*Acrothele pretiosa*.)
- Acrotreta* Kutorga, WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 4, Pl. XI, and pp. 142 and 146. (Classification of genus.)

The original description by Kutorga follows:

Dorsal valve highly conical; the hinge surface of the cone flat, in the form of a high triangle, similar to an area, with a shallow gutter-shaped depression running from the tip as far as the middle point, which (depression) here appears as an indication of a deltidium. At the upper end of this furrow, turned consequently to the hinge side, is found the obtusely oval external siphonal opening.

Ventral valve flat, with a distinct marginal apex. On the surface of the shell are seen only delicate growth wrinkles concentric to the apex of the cone, which curve crescentially into the longitudinal furrow of the surface of the shell; no tubercles and no spines; hinge border rectilinear.

The revised description of the genus is as follows: Ventral valve strongly convex to conical, with the posterior face more or less flattened to form a false area that is usually marked by a shallow median groove. Pedicle opening at the apex of the cone and directed more or less backward. Apex usually anterior to the posterior margin, but occasionally overhanging it. Dorsal valve slightly convex, with very small beak; area short and divided by a small false deltidium.

Surface marked by fine concentric striæ and lines of growth which cross the posterior face and the median groove; in addition there are on five species very fine, concentric, undulating, often inosculating, rounded ridges that form a surface like that of *Obolus* (*Westonia*) *ella* (Hall and Whitfield) (Pl. XLVII, fig. 10). *Acrotreta primæva* Walcott (Pl. LXIX) has this type of surface. *A. claytoni* Walcott (Pl. LXXIV) has fine, undulating striæ, *A. spinosa* Walcott (Pl. LXXIX) fine short spines, and *A. ? cancellata* Walcott (Pl. LXXIX) a cancellated surface. The shell in all species where it is preserved is calcareoconchous and built up of several thin layers or lamellæ that are arranged more or less obliquely to the outer surface toward the outer margin of the valves.

The cast of the ventral valve shows that the interior of the shell has a rather strong callosity or apical swelling penetrated by the foraminal tube, and on each side of and back of the callosity near the posterior margin the cardinal muscle scars, which usually take the form of a projecting boss or tubercle corresponding to a depression in the shell in which the transmedian and middle lateral muscles were probably attached. In front of the apical callosity in *A. argenta* Walcott there are two trapezoidal areas corresponding to similar areas in *Obolella* and *Obolus*, in which the central, outside, and middle lateral muscles were attached. The position and size of the areas are shown by Plate LXVII, figures 5a and 5b. The grooves of the main vascular sinuses pass around the apical swelling and extend forward, diverging toward the anterolateral margins of the shell.

The interior of the dorsal valve is almost invariably marked by a long, well-defined median ridge and a pair of strong cardinal tubercles near the margin of the area corresponding in position to the cardinal tubercles of the ventral valve. Smaller tubercles occur in advance of the posterior tubercles, one on each side of the median ridge; they are often replaced by elongate oval scars that correspond to the central scars of the dorsal valve of *Obolus*: the anterior lateral muscle scars are too minute to be clearly located, but they were undoubtedly close to the median line a little in advance of the central scars. The cardinal tubercles of both valves often have scars on them indicating the attachment of muscles.

Type.—*Acrotreta subconica* Kutorga.

Observations.—Of the type of the genus, *A. subconica* Kutorga, only the external shell is known. In 1884 [1884b, Pl. I, figs. 1b and 1d] I illustrated the interior of both valves of "*A. gemma*" (see pp. 30–31), showing the area, median ridge, "cardinal tubercles," and central muscle tubercles of the dorsal valve, and the apical swelling and cast of the main vascular canals in the ventral valve. Matthew [1886, Pl. V, figs. 13 and 13c] illustrated the interior of *A. baileyi*, showing the cast of a small tubercle on each side of the apical swelling. Hall and Clarke [1892c, p. 102] stated that they could not see the cast of these tubercles on the original specimen, and I have not been able to find them on any of the type specimens of *A. baileyi* received from Matthew. It frequently occurs that the casts of the short deep channel of the main vascular sinuses give rise to tubercles a little in advance of and close to the apical callosity (Pl. LXX, fig. 1f), or it may be that the cast of the visceral cavity will take the form of tubercles in front of the cast of the apical callosity (Pl. LXIV, fig. 2c).

The intimate relations existing between *Acrotreta* and *Linnarssonina* became more and more apparent with the collection of better material representing the two species referred to the two genera. Girty, when selecting specimens for illustration, called my attention to the strong resemblance between them and suggested that *Linnarssonina* was a synonym of *Acrotreta*. In all essential characters this is true, and *Linnarssonina*, if retained at all, must be as a subgenus to include the depressed forms of *Acrotreta*, intermediate between the typical elevated species *A. subconica* Kutorga and *A. gemma* Billings and the nearly flattened shells of *Acrothele*. In view, however, of the close similarity of the interiors of the valves of *Acrotreta schmalensei* Walcott, *A. curvata* Walcott, and *A. kutorgai* Walcott to "*Linnarssonina transversa*" (see *Acrotreta sagittalis transversa* (Hartt)), "*L. sagittalis* (Salter), and "*L. misera* (Billings) there remains only the external form of the pedicle valve to distinguish the two genera; this latter character is not of generic importance in the presence of the gradation in elevation and outline between *A. subconica* Kutorga and *A. sagittalis transversa* (Hartt), shown by *A. idahoensis* Walcott, *A. schmalensei* Walcott, *A. microscopica* (Shumard), *A. pyxidicula* White, and *A. sagittalis* (Salter).

When studying the specimens of *Acrotreta* at hand in 1884 I believed that *A. gemma* Billings, of Newfoundland, included the western forms described by Meek [1873, p. 463] and White [1877, p. 53]. This conclusion was retained until the study of a large series from each of the typical localities convinced me that there were a number of species and varieties grouped under *A. gemma*. The correct reference of these species and varieties is indicated in the table, pages 30–31, and taken up in detail in the synonymy of each of the different species.

"*Acrotreta? costata*" Davidson [1883, p. 213] from the Llandeilo of Scotland does not appear to be an *Acrotreta*. The description and figures suggest a genus allied to *Cyrtia* Hall and Clarke [1894, p. 40] of the Silurian.

The surface characters of *Acrotreta* have been considered to be very simple and confined to concentric lines and striæ of growth and obscure radiating striæ. This study of the species has resulted in the discovery that five species, *A. bisecta* Matthew, *A. gemmula* Matthew, *A. inflata* (Matthew), *A. primæva* Walcott, and *A. sabinæ* (Callaway), have a surface much like that of *Obolus* (*Westonia*) *ella* (Hall and Whitfield) (Pl. XLVII). Mention has been made of the cancellated and spinose species, and those with undulating concentric striæ. It is evident that *Acrotreta*, like *Acrothele* and *Micromitra*, has varied surface characters that are of specific but not generic value.

The false area, with or without its vertical median groove, is a variable character. The area and median groove are well developed in the type *A. subconica* Kutorga (Pl. LXXIII, figs. 2g, 2h) and in the species *A. socialis* v. Seebach (Pl. LXXIII, figs. 4', 4a'). On *A. attenuata* Meek a narrow sharp furrow is present, but the false area is scarcely defined (Pl. LXIV, figs. 1b'', 1c'', 1d''). On *A. idahoensis* Walcott the false area is clearly defined but there is scarcely a trace of the median furrow (Pl. LXV, figs. 1'', 1a''-c''). On *A. microscopica* (Shumard) (Pl. LXVII, figs. 1a'-c') there is only a faint false area and no median groove.

The vascular markings, muscle scars, and apical callosity of the ventral valve vary in relative size, position, and appearance, but they all have a common general character and position. Usually the markings on the interiors of the valves are very faint, and often nothing can be seen but the apical callosity and the base of the main vascular sinuses in the ventral valve, and the median ridge in the dorsal valve. It would require many pages on which to record the variations, and as they are illustrated by the figures on the plates I will not attempt it.

Geographic distribution.—The little shell of *Acrotreta* occurs in every country where any considerable development of the Cambrian fauna is known. The exceptions are northern India, Australia, and where the Lower Cambrian fauna predominates. The general distribution is given on pages 105-106.

Stratigraphic distribution.—Three species and one variety are known from the Lower Cambrian, one of which, *A. primæva* Walcott (Pl. LXIX, figs. 1, 1a-f), is one of the largest species of the genus. From the Middle Cambrian thirty-three species and ten varieties are known; they range from the base of the terrane to its summit, and two, *A. idahoensis* Walcott and its variety *alta* and *A. pyridicula* White, pass up into the Upper Cambrian, and the first species and its variety *alta* continue on up into the base of the Ordovician in Nevada. In the Upper Cambrian twenty-one species and three varieties are known and in the passage beds above seven species. In the Lower Ordovician seven species and one variety occur, of which one species and one variety also occur in the Cambrian. The stratigraphic range of the species is given on pages 105-106.

ACROTRETA ARGENTA Walcott.

Plate LXVII, figures 5, 5a-g.

Acrotreta argenta WALCOTT, 1902, Proc. U. S. Nat. Mus., vol. 25, pp. 580-581. (Described as below as a new species.)

The material representing this species is more or less crushed and broken, but a few specimens show the general form and characters. It belongs to the *Acrotreta idahoensis* Walcott group in having a wide false area, strongly marked apical callosity, and pedicle opening. The thickening in the posterior portion of the dorsal valve is also characteristic of the two species.

The cast of the interior of a ventral valve (Pl. LXVII, fig. 5b) reveals what I have searched for unsuccessfully in hundreds if not thousands of specimens of this genus. I refer to the visceral area with the position of the point of attachment of the central and lateral muscles on each side of it, essentially as in *Obolella* and *Obolus* (Pl. VII).

FORMATION AND LOCALITY.—Upper Cambrian: (7x and 7y) Limestone of the Emigrant formation [Turner, 1902, p. 265], about 2.5 miles (4 km.) southeast of Emigrant Pass; (8b') shales of the Emigrant formation [Turner, 1902, p. 265],

in a ravine on the east side of the road about 1 mile (1.6 km.) southwest of Emigrant Pass; and (7v) shales of the Emigrant formation [Turner, 1902, p. 265], 4.25 miles (6.8 km.) south-southeast of Emigrant Peak; all in the Silver Peak quadrangle (U. S. Geol. Survey), Esmeralda County, Nevada.

ACROTRETA ATTENUATA Meek.

Plate LXIV, figures 1, 1a-o; Plate LXXIX, figures 6, 6a.

- Acrotreta attenuata* MEEK (in part), 1873, Sixth Ann. Rept. U. S. Geol. and Geog. Survey Terr. for 1872, p. 463, footnote. (Listed as *A. subconica* Kutorga, and described in footnote as a possible new species. Specimens now referred to *A. attenuata* var.? and *A. idahoensis* were also included in this reference.)
- Acrotreta gemma* WALCOTT (in part) [not BILLINGS], 1884, Mon. U. S. Geol. Survey, vol. 8, pp. 17-18. (Specimens representing *Acrotreta pyridicula*, *A. curvata*, and *A. idahoensis alta* were included with the specimens representing *A. attenuata* when this description of *A. gemma* was written, but only the last two are known to have been figured: *A. curvata*, Pl. I, figs. 1d and 1e; and *A. idahoensis alta*, Pl. I, figs. 1a and 1b. The specimens represented by Pl. IX, figs. 9 and 9a, can not be found at this time, but it is probable that they should be referred to *A. idahoensis alta*. Fig. 1c represented a specimen of *Acrotreta sabrinæ*, and the specimen represented by fig. 1f is missing.)
- Acrotreta gemma* WALCOTT (in part) [not BILLINGS], 1886, Bull. U. S. Geol. Survey No. 30, pp. 98-99. (Specimens now referred to *Acrotreta pyridicula* and *A. primæva* were included with the specimens representing *A. attenuata* when this description of *A. gemma* was written, *A. primæva* being figured, Pl. VIII, figs. 1, 1a-b.)
- Acrotreta gemma* WALCOTT (in part) [not BILLINGS], 1891, Tenth Ann. Rept. U. S. Geol. Survey, p. 608. (Specimens now referred to *Acrotreta pyridicula*, *A. curvata*, *A. idahoensis alta*, and *A. primæva* were included with the specimens representing *A. attenuata* in this reference to *A. gemma*, the last three being figured: *A. curvata*, Pl. LXVII, fig. 5b; *A. idahoensis alta*, Pl. LXVII, figs. 5 and 5a; and *A. primæva*, Pl. LXVII, figs. 5c, 5d, and 5e.)
- Acrotreta gemma* WALCOTT (in part) [not BILLINGS], 1899, Mon. U. S. Geol. Survey, vol. 32, pt. 2, p. 449. (Specimens now referred to *Acrotreta pyridicula*, *A. curvata*, *A. idahoensis alta*, and *A. primæva* were included with the specimens representing *A. attenuata* when this description of *A. gemma* was written, the last three being figured: *A. curvata*, Pl. LXII, fig. 2e; *A. idahoensis alta*, Pl. LXII, figs. 2a and 2c; and *A. primæva*, Pl. LXII, figs. 2, 2b, and 2d.)
- Acrotreta attenuata* Meek, WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 298. (Characterized.)

The variations in the exterior form of the ventral valve of this species are so fully shown by the illustrations that it is unnecessary to enter into detailed description. The species is characterized by its elevated ventral valve and narrow, incurved false area. The specimens illustrated by Plate LXIV, figures 1, 1a, 1b, and 1h, are from the material labeled by Meek as *Acrotreta attenuata*, and all the others are from the same geological area. Some of the forms of *A. idahoensis alta* (Pl. LXV, fig. 4) look like *A. attenuata*, but the false area is different. *Acrotreta kutorgai* has a somewhat similar false area and elevation, but it is a less robust shell and the apex of the ventral valve is nearer the posterior margin. The former reference to *A. gemma* is explained under the description of the genus (p. 673). Shells with a distinctly marked false pedicle groove in the ventral valve occur in the shales of the Wheeler formation of the Middle Cambrian of the House Range, Utah. The shells of this locality show fine interiors of both valves (Pl. LXIV, figs. 1i-n, and Pl. LXXIX, figs. 6, 6a). The interiors of the ventral valve are much like those of *A. kutorgai* Walcott (Pl. LXV, figs. 3b, 3c).

FORMATION AND LOCALITY.—Upper Cambrian: (61) Limestone in the Dunderberg shale [Walcott, 1908f, p. 184], a little south of the Hamburg mine, Eureka district [Hague, 1892, Atlas], Eureka County, Nevada.

Middle Cambrian: (59) Limestone at the base of the western slope of Combs Peak, near the plain of Antelope Valley, Eureka district [Hague, 1892, Atlas], Eureka County, Nevada.

(3s) About 1,700 feet (518.2 m.) above the Lower Cambrian and 2,700 feet (823 m.) below the Upper Cambrian in the shaly limestones and calcareous shales of the Wheeler formation [Walcott, 1908f, p. 181] in the eastern part of Wheeler Amphitheater, east of Antelope Springs, House Range [Walcott, 1908f, Pls. XIII and XV]; (10y) about 2,900 feet (884 m.) above the Lower Cambrian and 1,500 feet (457.2 m.) below the Upper Cambrian in the central part of the limestone forming 1a of the Marjum limestone [Walcott, 1908f, p. 179], about 1 mile (1.6 km.) south-southwest of Marjum Pass, House Range [Walcott, 1908f, Pl. XIII]; and (3x) about 2,200 feet (670.6 m.) above the Lower Cambrian and 2,200 feet (670.6 m.) below the Upper Cambrian in the shaly limestones forming 1d of the Marjum limestone [Walcott, 1908f, p. 180], 2.5 miles (4 km.) east of Antelope Springs, in ridge east of Wheeler Amphitheater, House Range [Walcott, 1908f, Pls. XIII and XV]; all in Millard County, Utah.

(9h) At the base of the limestone above the Wolsey shale [Walcott, 1908f, p. 202] on Beaver Creek, 5 miles (8 km.) north of York, and about 8 miles (12.8 km.) north of Canyon Ferry, Big Belt Mountains, Fort Logan quadrangle (U. S. Geol. Survey), Meagher County; (159) limestones north of West Gallatin (Gallatin) River, Gallatin County; (302)

limestones on the east side of West Gallatin (Gallatin) River, above Gallatin, Gallatin County; and (156a) limestones of the Flathead formation of Peale, north of East Gallatin River, near Hillsdale, Gallatin County; all in Montana.

(4n) Limestone about 325 feet (99.1 m.) above the unconformable base of the Cambrian in divide at the head of Jackson Creek (locally known as Sheep Creek), a creek flowing into Jackson Lake about 0.5 mile (0.8 km.) south of its northwest corner, Teton Mountains, Grand Teton quadrangle (U. S. Geol. Survey), Uinta County; and (340d) limestone near the head of Bear River Canyon; both in Wyoming.

ACROTRETA ATTENUATA var.? Walcott.

Plate LXV, figure 2.

Acrotreta attenuata MEEK (in part), 1873, Sixth Ann. Rept. U. S. Geol. and Geog. Survey Terr. for 1872, p. 463, footnote. (These specimens were included by Meek with the specimens which he listed as *Acrotreta subconica* and described in a footnote as *A. attenuata*. See also *A. attenuata* and *A. idahoensis*.)

Acrotreta attenuata Meek, var.?, WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 298. (Reason given for separation as variety.)

A shell with a distinctly marked false area is separated as a variety of *Acrotreta attenuata*. It is associated with the type specimen of *A. attenuata*.

FORMATION AND LOCALITY.—Middle Cambrian: (302) Limestone east of West Gallatin (Gallatin) River, above Gallatin, Gallatin County, Montana.

ACROTRETA BABEL Barrande.

Plate LXXVII, figures 6, 6a-b.

Acrotreta babel BARRANDE, 1879, Système silurien du centre de la Bohême, vol. 5, pt. 1, Pl. XCV, figs. VII: 1-2. (Not described, but figured as a new species. Figs. 2A, 2B, and 2C are reproduced in this monograph, Pl. LXXVII, figs. 6, 6a-b, respectively.)

This minute species is the only form of this genus that has been identified from Bohemia by Barrande. It has the characters of the genus, and with the figures for comparison with other species it appears to be distinct from all others. Barrande [1879b, Pl. XCV, fig. VII: 1] illustrates a more conical shell from Trubin than that represented by figures 6 and 6a, which may belong to another species and genus.

FORMATION AND LOCALITY.—Lower Ordovician: (303) Étage d3, Königshof; and (303a) Étage d3, Trubin; both [Barrande, 1879b, Pl. XCV] in Bohemia, Austria-Hungary.

ACROTRETA BAILEYI Matthew.

Plate LXXVII, figures 2, 2a-d.

Acrotreta baileyi MATTHEW, 1886, Trans. Roy. Soc. Canada for 1885, 1st ser., vol. 3, sec. 4, No. 4, pp. 36-37, Pl. V, figs. 13, 13b-d. (Described and discussed as a new species. The specimens represented by figs. 13, 13c, and 13d are redrawn in this monograph, Pl. LXXVII, figs. 2a, 2, and 2', respectively.)

Acrotreta baileyi Matthew, HALL and CLARKE, 1892, Eleventh Ann. Rept. State Geologist New York for 1891, Pl. III, figs. 28-30. (Figs. 28 and 30 are drawn from the specimens figured by Matthew, 1886, Pl. V, figs. 13c and 13, respectively.)

Acrotreta baileyi Matthew, HALL and CLARKE, 1892, Nat. Hist. New York, Paleontology, vol. 8, pt. 1, p. 102, Pl. III, figs. 32-34. (Discussed. Figs. 32-34 are copied from figs. 28, 30, and 29 of the preceding reference.)

Not *Acrotreta baileyi*? MATTHEW, 1892, Trans. Roy. Soc. Canada for 1891, 1st ser., vol. 9, sec. 4, No. 5, p. 43, Pl. XII, fig. 7d (referred to *A. bisecta*).

Acrotreta baileyi MATTHEW, 1902, Bull. Nat. Hist. Soc. New Brunswick, vol. 4, pt. 5, No. 20, p. 395, Pl. XVI, figs. 1a-d. (Mentioned and dimensions given. Figs. copied from Matthew, 1886, Pl. V, figs. 13, 13b-d.)

Acrotreta baileyi Matthew, WALCOTT, 1902, Proc. U. S. Nat. Mus., vol. 25, pp. 581-582. (Described and discussed as below.)

Acrotreta baileyi MATTHEW, 1903, Geol. Survey Canada, Rept. Cambrian Rocks Cape Breton, p. 97, Pl. III, figs. 1a-d. (Mentioned. Figures are copied from Matthew, 1886, Pl. V, figs. 13, 13b-d.)

General outline transversely oval, with the posterior margin more or less straight for less than one-half the transverse diameter of the shell. On the ventral valve the posterior margin is rounded in at the median furrow of the false area, and on the dorsal valve it curves gently from the cardinal slopes to the beak.

The ventral valve is strongly convex with the apex about one-fourth the length of the valve from the posterior margin. The crushed condition of the shells does not permit

decision as to whether the umbo or the apex is the most elevated part of the valve. False area defined by the incurving of the cardinal slopes so as to form a somewhat flattened, triangular space that is divided midway by a rather strong vertical furrow. Pedicle aperture rather large and opening obliquely backward. The dorsal valve is gently convex, with a minute marginal beak.

Surface of shell marked by fine concentric striæ and lines of growth, and possibly by fine radiating striæ. I fail to find any traces of the radiating striæ on specimens that have not been distorted by pressure, and it looks as though all radiating striæ and lines are the result of lateral compression of the shell. The average length is about 3.5 mm.; width, 4 mm. (Distorted shells have a length of 4 mm.; width, 3 mm.)

The cast of the interior of the ventral valve shows a strong apical callosity, a fair-sized pedicle opening, large cardinal scars, and a small visceral area in front of the apical callosity. Matthew [1886, p. 36, Pl. V, fig. 13c] describes and shows on his illustration two "minute muscle scars" close to the "umbonal tubercle" and on each side of the parallel striæ. On one specimen I find what may have led Matthew to consider there were such scars, but on many others quite as well preserved there are no such indications, and they are not known in any other species of the genus. Hall and Clarke examined Matthew's type material, and stated [1892c, p. 102] that with the original material before them they were unable "to distinguish anything more than the central callosity." The cast of the interior of the dorsal valve shows a strong median ridge of variable length and size, large cardinal scars, and well-defined central scars.

Observations.—This species belongs with the series represented by *A. sagittalis* (Salter) and its varieties, and if uncompressed, nondistorted, well-preserved specimens could be obtained, it is quite possible that it would prove to be identical with *A. sagittalis transversa* (Harit). Matthew [1886, p. 37] thinks it has a thinner shell, but that is not probable, as the apical callosity and cardinal scars of the ventral valve and the median ridge, cardinal and central scars of the dorsal valve all indicate a shell quite as thick as that of *A. sagittalis* and its varieties.

Doctor Matthew kindly sent me the type and study material of this species from his private collection.

FORMATION AND LOCALITY.—Middle Cambrian: (300) *Shaly sandstones, possibly of Division 1d of Matthew, on Long Reach, Kings County*; and (301) doubtfully in sandstones of Division 1b2 of the "Protolenus zone" [Matthew, 1895a, p. 108] Hanford Brook, St. John County; both [Matthew, 1886, p. 37] in New Brunswick, Canada.

ACROTRETA BELLATULA Walcott.

Plate LXXVIII, figures 4, 4a-d.

Acrotreta bellatula WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 3, pp. 93-94, Pl. IX, figs. 4, 4a-b. (Described and discussed as below as a new species. Figs. 4, 4a-b are copied in this monograph, Pl. LXXVIII, figs. 4, 4b, and 4d, respectively.)

General outline subcircular to transversely broad oval, with the posterior margin of the ventral valve nearly straight beneath the false area. The ventral valve is moderately convex, with the apex a little in front of the posterior margin. False area defined by the incurving of the cardinal slopes so as to form a somewhat flattened triangular space that is divided midway by a narrow and rather shallow, vertical furrow; pedicle aperture of medium size and opening slightly backward. Dorsal valve nearly as convex as the ventral, except that it curves down in the posterior portion to a minute marginal beak.

Surface of the shell marked by fine, concentric striæ and lines of growth that show marked variations in their sharpness on different specimens, the older shells having a dark, dull surface giving the effect of a thin film over the striæ; a few traces of radiating striæ are shown on some shells.

The average length of the larger shells is about 1.75 mm.; width, 2 mm.

The interior of the ventral valve shows a small apical callosity, minute pedicle tube, and vascular sinuses originating a little back of the apical callosity; a cast shows that there were

medium-sized, elevated cardinal muscle scars. An interior cast of the dorsal valve indicates a median ridge that extended about four-fifths of the distance from the area to the front margin. It also indicates medium-sized, elevated cardinal muscle scars. A second specimen shows a shorter median ridge, with small, elevated central muscle scars about halfway between the posterior and front margins of the shell.

Observations.—This species belongs to the *Acrotreta sagittalis* (Salter) group. The low convexity of the ventral valve, posterior position of the apex, the strong cardinal muscle scars, and the strong median ridge, and the cardinal and central scars of the dorsal valve, are all features common to *Acrotreta bellatula* and *A. sagittalis*. It differs from *A. sagittalis* in the more posterior position of the apex and less convexity of the ventral valve, and from *A. definita* Walcott in its much smaller size and less elevated ventral valve.

FORMATION AND LOCALITY.—**Middle Cambrian:** (10z) About 2,900 feet (884 m.) above the Lower Cambrian and 1,500 feet (457.2 m.) below the Upper Cambrian in 1a of the Marjum limestone [Walcott, 1908f, p. 179]; (11a) a horizon about 100 feet (30.5 m.) above (10z); and (3w) about 2,350 feet (716.3 m.) above the Lower Cambrian and 2,050 feet (624.8 m.) below the Upper Cambrian in the central portion of 1c of the Marjum limestone [Walcott, 1908f, p. 180], in the long cliff about 2 miles (3.2 km.) southeast of Marjum Pass; both in the House Range [Walcott, 1908f, Pls. XIII and XV], Millard County, Utah.

ACROTRETA BELTI (Davidson).

Plate LXXVII, figures 8, 8a.

Obolella belti DAVIDSON, 1868, Geol. Mag., vol. 5, pp. 310–311, Pl. XV, figs. 25–27. (Described as below as a new species. The specimens represented by figs. 25–27 are redrawn by Davidson, 1871, Pl. L, figs. 15, 17, and 16, respectively, and the last two figures are copied in this monograph; see note accompanying the following reference.)

Obolella belti DAVIDSON, 1871, British Fossil Brachiopoda, vol. 3, pt. 7, No. 4, pp. 340–341, Pl. L, figs. 15–17. (Copy of preceding reference; figs. 15–17 are copied (with slight changes) from figs. 25, 27, and 26, respectively, of the preceding reference. Figs. 16a and 17a are reproduced in this monograph, Pl. LXXVII, figs. 8 and 8a, respectively.)

Obolella sagittalis belti DAVIDSON, 1871, idem, description of figures, opposite Pl. L. (Species placed as a variety without explanation.)

Not *Linnarssonina belti*? MATTHEW, 1892, Trans. Roy. Soc. Canada for 1891, 1st ser., vol. 9, sec. 4, No. 5, pp. 42–43, Pl. XII, figs. 7a–c. (This species is not specifically referred in this monograph.)

Linnarssonina belti (Davidson), MATLEY, 1902, Quart. Jour. Geol. Soc. London, vol. 58, pt. 1, p. 145, figs. 17–18. (Characterized.)

Not *Linnarssonina* cf. *belti* MATTHEW, 1903, Geol. Survey Canada, Rept. Cambrian Rocks Cape Breton, pp. 209–210, Pl. XVI, figs. 3a–c. (Copies Matthew, 1892, pp. 42–43, Pl. XII, figs. 7a–c. The species is not specifically referred in this monograph.)

The original description by Davidson follows:

Shell small, less than a line in length by about 1 line in breadth; transversely oval; beak acuminate; front broadly rounded. Valves moderately convex and marked by concentric lines of growth. The internal characters agree pretty closely with those described in *O. sagittalis*.

Observations.—It is possible that with a good series of specimens of this species its relations to other species might be more accurately determined than Doctor Davidson was able to do. It is not probable that *Acrotreta sagittalis* (Salter) persisted into Lower Tremadoc time, but with a genus where the specific characters are so limited and the variations within the same species considerable it is exceedingly difficult to determine the specific relations of a form represented by only a few not very good specimens. *Acrotreta belti* appears to belong to the *A. sagittalis* group of forms, but for the present I think it is quite as well to leave it as a species.

FORMATION AND LOCALITY.—**Upper Cambrian:** (305 [Davidson, 1871, p. 341]) Lower Tremadoc shales, Craig-y-dinas, North Wales.

(304 [Matley, 1902, p. 145]) “Bronsil” shales at White Leaved Oak, Malvern Hills; and (304a [Groom, 1902, p. 110]) “Bronsil” shales in the Malvern Hills; both between Herefordshire and Worcestershire, England.

ACROTRETA BISECTA Matthew.

Plate LXVI, figures 7, 7a–e.

Acrotreta baileyi? MATTHEW, 1892, Trans. Roy. Soc. Canada for 1891, 1st ser., vol. 9, sec. 4, No. 5, p. 43, Pl. XII, fig. 7d. (Characterized and discussed.)

Acrotreta bisecta MATTHEW, 1901, Bull. Nat. Hist. Soc. New Brunswick, vol. 4, pt. 4, No. 19, pp. 275–276, Pl. V, figs. 5a–g. (Described and discussed as a new species.)

- Acrotreta bisecta* MATTHEW, 1902, Bull. Nat. Hist. Soc. New Brunswick, vol. 4, pt. 5, No. 20, p. 394, Pl. XVI, figs. 2a-g. (Mentioned and figures of preceding reference copied.)
- Acrotreta sipo* MATTHEW, 1902, idem, pp. 406-407, Pl. XVIII, figs. 1 and 2. (Described and discussed as a new species.)
- Acrotreta bisecta* MATTHEW, WALCOTT, 1902, Proc. U. S. Nat. Mus., vol. 25, p. 582. (Described and discussed.)
- Acrotreta sipo* MATTHEW, 1903, Geol. Survey Canada, Rept. Cambrian Rocks Cape Breton, pp. 185-186, Pl. XVIII, figs. 1 and 2. (Copy of Matthew, 1902a, pp. 406-407, Pl. XVIII, figs. 1 and 2.)
- Acrotreta bisecta* MATTHEW, 1903, idem, pp. 186-187, Pl. XI, figs. 5a-g. (Copy of Matthew, 1901, pp. 275-276, Pl. V, figs. 5a-g.)
- Acrotreta bisecta* MATTHEW, WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 298-299. (Described and discussed as below.)

Nearly all the ventral valves of this species are more or less compressed in the shale, thus decreasing the true elevation. Matthew [1903, Pl. XI, fig. 5] illustrates a pointed, high, ventral valve, but does not state whether or not the figure is diagrammatic. Some of the casts in the shale indicate a sharply conical ventral valve. When the apex is broken off the cast of a median apical callosity is seen, with the base of the cast of a medium-sized pedicle tube; the cardinal scars are small and nearly concealed by the cast of the strong main vascular sinuses. There is considerable range of variation in the size and length of the median ridge of the dorsal valve. One specimen (fig. 7d) shows a strong median ridge, cardinal and central scars, and deeply excavated false deltidium. Surface marked by fine concentric striæ and lines of growth and very fine undulating striæ that give the concentric striæ a fretted appearance when examined by a strong lens.

The most nearly related species appears to be *A. sabrinæ* (Callaway) of the Shineton shales. Matthew [1902a, p. 406] has described a shell as "*Acrotreta sipo*" that occurs with his "*Asaphellus* fauna." I am unable to detect any specific differences between it and *A. bisecta*, from the same area.

The specific name is due to the presence of a strong median ridge bisecting the dorsal valve.

FORMATION AND LOCALITY.—Upper Cambrian: (3q) Shale in Barachois Glen, 4 miles (6.4 km.) south of Little Bras d'Or Lake; (101) shale on east bank of Barachois River, 6 miles (9.6 km.) from Little Bras d'Or Lake; (10c and 10d) shales on west side of Barachois River, 0.125 mile (0.2 km.) north of Boisdale Road, opposite McMullin's place; (10e, 10f, and 10g) shales on the east branch of Barachois River, 0.5 and 0.75 miles (0.8 and 1.2 km.), respectively, north of the crossroad from Boisdale to Upper Leitches Creek; (10n) shale in ravine on east side of Barachois Glen, 3 miles (4.8 km.) from Barachois; (10h) shale on small east branch of Barachois River, 0.75 mile (1.2 km.) north of the crossroad from Boisdale to Upper Leitches Creek; (13h) shale on east bank of Barachois River, 1.5 miles (2.4 km.) north of Boisdale; (307a [Matthew, 1903, p. 186]) shales of Division C3c2 of Matthew, on McLeod Brook=Barachois River; and (307 [Matthew, 1903, p. 187]) shales of Division C3c of Matthew, on McLeod Brook=Barachois River; all in eastern Cape Breton, Nova Scotia.

(308 [Matthew, 1892, p. 43]) Shales of Division C3c of Matthew at Navy Island, St. John Harbor, New Brunswick, Canada.

ACROTRETA?? CANCELLATA Walcott.

Plate LXXIX, figures 5, 5a.

Acrotreta?? cancellata WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 299. (Characterized as below as a new species.)

The only specimen of this species in the collection has more the form of *Micromitra* than *Acrotreta*. In its overhanging false area it suggests *Acrothyra*. Whatever the genus to which it belongs may be, its cancellated surface serves to distinguish it from forms with which it might otherwise be compared. The surface is formed by very fine, raised, concentric lines or ridges of growth, crossed by sharp radiating lines, which are seen only between the concentric lines.

FORMATION AND LOCALITY.—Passage beds between the Upper Cambrian and the Ordovician: (205) Siliceous limestone on Roundtop Mountain, Eureka district [Hague, 1892, Atlas], Eureka County, Nevada.

ACROTRETA CARINATA (SEGERBERG MS.) Moberg and Segerberg.

Text figures 56A-D, page 680.

Acrotreta cf. *socialis* BRÖGGER (in part), 1882, Die silurischen Etagen 2 und 3, pp. 46-47, Pl. X, figs. 2, 2a-b (not figs. 3-4, which are not referred in this monograph). (Described in German.)

Acrotreta carinata (SEGERBERG MS.) MOBERG and SEGERBERG, 1906, Medd. från Lunds Geol. Fältklubb, Ser. B, No. 2 (Afttryck ur K. Fysiografiska Sällskapet's Handl., N. F., Bd. 17), p. 66, Pl. III, figs. 5a-c and 6. (Described in Swedish as a new species; see p. 680 for translation. The figures are reproduced in this monograph as figs. 56A-D, p. 680.)

The original description by Moberg and Segerberg follows:

The species differs from *Acrotreta circularis*, to which in other respects it is closely related, by its more even area, sharply bounded on the sides. At the rectilinear posterior edge the area occupies about one-fourth of the circumference; that is to say, more than in the case of *A. circularis*. The apex is also placed somewhat nearer the posterior edge than in the last-named species. The smaller shell is only feebly arched, with marginal, somewhat overlapping umbo.

By its large well-marked keeled area our species resembles *A. socialis*, from the *Ceratopyge* limestone of Norway.

Observations.—This species has about the same size and general appearance as *Acrotreta seebachi*. It differs from it in the more anterior position of the apex and the strongly defined false area with a median ridge.

FORMATION AND LOCALITY.—*Passage beds* between the Cambrian and the Ordovician: (310) *Ceratopyge* limestone (zone 4), at Ottenby, on Oeland Island; and (309) *Ceratopyge* limestone (zone 4), at Fogelsång, 5 miles (8 km.) east of Lund, Province of Malmöhus; both [Moberg and Segerberg, 1906, p. 66] in Sweden.

FIGURE 56.—*Acrotreta carinata* Moberg and Segerberg. A, Top view of ventral valve. B, Back view of ventral valve. C, Side view of ventral valve. D, Dorsal valve. All $\times 8$. The ventral is the type.

The specimens represented are from Locality 309, the *Ceratopyge* limestone at Fogelsång, Province of Malmöhus, Sweden. The figures are copied from Moberg and Segerberg [1906, Pl. III, figs. 5a-c and 6].

The original description by Moberg and Segerberg follows:

The apex of the larger shell (ventral valve) is situated midway between the posterior edge and the center, or possibly (the apex itself is not preserved) somewhat closer to the center. On the posterior edge there is a slightly defined triangular area which has a median rounded ridge extending out from the apex. The area as a whole is also somewhat arched, not quite level; at the posterior edge it occupies about one-fifth of the entire circumference of the shell. The height (from the apex to the level of the edge of the shell) is about two-thirds of the breadth. Shell smooth, shiny, with fine concentric growth lines visible even on the area, where, however, they are feebler. On both sides of the apex where the shell, as above mentioned, has been removed, there is found a furrow which on the area is parallel with its nearest side edge, and in the opposite direction runs obliquely toward the side. In the direction from the apex down toward the anterior edge the shell is quite arched. The species differs from *Acrotreta socialis* von Seebach, as known from examples from the *forchhammeri* zone, by its greater size, its distinct keeled area, and the more subcentral position of the apex, which again causes the arch to be less raised.

Observations.—This shell is nearest to *Acrotreta seebachi* (Pl. LXXVII, figs. 3, 3a). It differs in having the apex farther back from the posterior margin and in the strong median ridge on the false area. It is very close to *Acrotreta carinata* Moberg and Segerberg.

FORMATION AND LOCALITY.—*Passage beds* between the Cambrian and the Ordovician: (310) *Ceratopyge* limestone (zone 4), at Ottenby, on Oeland Island; and (309) *Ceratopyge* limestone (zone 4), at Fogelsång, 5 miles (8 km.) east of Lund, Province of Malmöhus; both [Moberg and Segerberg, 1906, p. 66] in Sweden.

ACROTRETA CLAYTONI Walcott.

Plate LXXIV, figures 3, 3a-b.

Acrotreta claytoni WALCOTT, 1902, Proc. U. S. Nat. Mus., vol. 25, p. 583. (Described as below as a new species.)

The material representing this species does not give sufficient data for the preparation of a detailed description. The only ventral valve is depressed by compression in the shale; it is transversely broad oval in outline, with the posterior margin nearly straight for a distance of

ACROTRETA CIRCULARIS Moberg and Segerberg.

Text figures 57A-C.

Acrotreta circularis MOBERG and SEGERBERG, 1906, Medd. från Lunds Geol. Fältklubb, Ser. B, No. 2 (Afttryck ur K. Fysiografiska Sällskapets Handl., N. F., Bd. 17), pp. 65-66, Pl. III, figs. 4a-c. (Described in Swedish as a new species; see below for translation. The figures are reproduced in this monograph as figs. 57A-C.)

FIGURE 57.—*Acrotreta circularis* Moberg and Segerberg. A, Top view. B, Posterior view. C, Side view. All $\times 8$.

The specimen represented is from Locality 309, the *Ceratopyge* limestone at Fogelsång, Province of Malmöhus, Sweden. The figures are copied from Moberg and Segerberg [1906, Pl. III, figs. 4a-c].

two-fifths of the diameter of the valve; the false area is fairly well defined by the abrupt incurving of the cardinal slopes; its median furrow is distinctly outlined, and it slopes forward to the apex, which is situated about two-fifths the distance from the posterior margin to the front margin. Pedicle aperture minute and directed upward from the extreme apex of the valve. Dorsal valve gently convex. Surface of shell marked by fine concentric striæ and lines of growth, and very fine irregular, undulating striæ that can be seen only by the aid of a strong lens.

A partial cast of a dorsal valve from the same faunal horizon about 30 miles distant shows a well-defined median ridge and cardinal scars.

Observations.—This species is most nearly related to *Acrotreta primæva* Walcott of the upper *Olenellus* fauna, at Pioche, Nevada. It differs in having a less elevated ventral valve and in the more advanced position of the apex and foraminal aperture. All the specimens known are also smaller than the average of *A. primæva*, the largest being 3 mm. in width and 2.5 mm. in length.

The specific name is derived from Clayton Valley, near the type locality.

FORMATION AND LOCALITY.—**Lower Cambrian:** (41) Limestone in the Pioche formation [Walcott, 1908a, p. 11] on a ridge 2.5 miles (4 km.) northwest of the town of Cherry Creek, White Pine County, Nevada.

(175) Shales carrying *Olenellus* on the divide between Clayton and Fish Lake valleys, about 15 miles (24.2 km.) southwest of Silver Peak; (184) shales at the summit of the Silver Peak Range, 10 miles (16.1 km.) southwest of the town of Silver Peak; and (11) shales of No. 3 of the Silver Peak group, Barrel Spring section [Walcott, 1908f, p. 189^a], 2.5 miles (4 km.) south of Barrel Spring and 0.5 mile (0.8 km.) east of the road, in the extreme southeastern corner of the Silver Peak quadrangle; all in the Silver Peak quadrangle (U. S. Geol. Survey), Esmeralda County, Nevada.

ACROTRETA CONCENTRICA Walcott.

Plate LXXVII, figures 1, 1a-b.

Acrotreta concentrica WALCOTT, 1902, Proc. U. S. Nat. Mus., vol. 25, p. 583. (Described as below as a new species.)

Shell small, outline subcircular to transversely broad oval; apex of ventral valve nearly central; false area indicated by a slight flattening of the valve on the posterior side, and a distinctly marked, but very narrow, median furrow. The elevation of the valve is about one-half its diameter. The dorsal valve is slightly convex and its cast is marked by small cardinal scars and a narrow median ridge that extends to the anterior third of the shell. A ventral valve is 1.25 mm. in diameter, and one dorsal valve is 2 mm. in length.

Observations.—This species occurs at about the horizon of *Acrotreta kutorgai* Walcott but is distinguished from that species and all others by the central position of the apex of the ventral valve.

This form owes its specific name to the nearly central position of the apex of the ventral valve.

FORMATION AND LOCALITY.—**Middle Cambrian:** (96x) Limestone 1 mile (1.6 km.) north of Adairsville, 15 miles (24.2 km.) northwest of Cartersville, Cartersville quadrangle (U. S. Geol. Survey), Bartow County, Georgia.

ACROTRETA CONULA Walcott.

Plate LXXV, figures 2, 2a-b.

Acrotreta conula WALCOTT, 1902, Proc. U. S. Nat. Mus., vol. 25, p. 584. (Described as below as a new species.)

Shell small. Ventral valve eccentrically cone-shaped, with a broadly oval transverse aperture. The apex is situated at the posterior third of the distance between the front margin and the posterior edge of the slightly indicated false area. A minute pedicle aperture occurs at the summit of the apex. Dorsal valve convex, with the minute beak at the posterior margin. The cast shows a well-defined median ridge with the central muscle scars well back on the valve.

Surface marked by fine concentric striæ and lines of growth.

This form owes its specific name to the fact that the ventral valve is markedly cone-shaped.

FORMATION AND LOCALITY.—**Upper Cambrian:** (310a) Shales of *Olenus truncatus* zone, Oeland Island, Sweden.

^a The species mentioned occur at two slightly different localities (11 and 1v), none of the species being common to both localities.

ACROTRETA CONVEXA Walcott.

Plate LXVI, figures 6, 6a-c.

Acrotreta convexa WALCOTT, 1902, Proc. U. S. Nat. Mus., vol. 25, p. 584. (Described essentially as below as a new species.)

Shell small, subcircular, valves convex. Ventral valve most elevated at the low apex, which is above the slightly transverse posterior margin. Dorsal valve somewhat less convex than the ventral valve, with its greatest elevation at the posterior third; beak minute, marginal. Length and width of shell 1 mm. Shell substance very thin, but not proportionally thinner than other large forms. Surface marked by fine concentric striæ and lines of growth.

Casts of the interior of the ventral valve show a minute apical callosity and cardinal scars. The cast of the dorsal valve has a long median furrow and minute cardinal scars.

Observations.—This minute shell occurs in the shales and in a fine-grained interbedded sandstone of the Upper Cambrian. It is characterized mainly by the convexity of the dorsal valve and the relatively low ventral valve, characters that point to its descent from a form like *Acrotreta sagittalis*.

The cast of a dorsal valve represented by Plate LXVI, figure 6c, shows a great development of the cardinal muscle scars; this is abnormal or else the valve belongs to another species.

FORMATION AND LOCALITY.—Upper Cambrian: (3n) *Thin-bedded sandstone on Salmon River, Gillis Hill, 13 miles (20.9 km.) south of Marion Bridge; (10e) shales on east branch of Barachois River, 0.5 mile (0.8 km.) north of the cross-road from Boisdale to Upper Leitches Creck; (101) shale on east bank of Barachois River, 6 miles (9.6 km.) from Little Bras d'Or Lake; and (10i) shale in high bank on west side of Barachois River, just north of the Boisdale road; all in eastern Cape Breton, Nova Scotia, Canada.*

ACROTRETA CURVATA Walcott.

Plate LXVIII, figures 1, 1a-n.

Acrotreta gemma WALCOTT (in part) [not BILLINGS], 1884, Mon. U. S. Geol. Survey, vol. 8, pp. 17-18, Pl. I, figs. 1d and 1e (not figs. 1a, 1b, 1c, and 1f; see below). (Specimens now referred to *Acrotreta attenuata*, *A. pyxidicula*, and *A. idahoensis alta* were included with the specimens representing *A. curvata* when this description of *A. gemma* was written, *A. idahoensis alta* being figured (Pl. I, figs. 1a and 1b). The specimens represented by Pl. IX, figs. 9 and 9a, can not be positively located at this time, but it is probable that they should be referred to *A. idahoensis alta*. The specimens represented by Pl. I, figs. 1d and 1e, are redrawn in this monograph, Pl. LXVIII, figs. 1g and 1h, respectively. Fig. 1c represented a specimen of *Acrotreta sabrinæ*, and the specimen represented by fig. 1f is missing.)

Acrotreta gemma WALCOTT (in part) [not BILLINGS], 1891, Tenth Ann. Rept. U. S. Geol. Survey, p. 608, Pl. LXVII, fig. 5b (not figs. 5, 5a, 5c, 5d, and 5e; see below). (Fig. 5b is a copy of Fig. 1d of preceding reference. Specimens now referred to *Acrotreta attenuata*, *A. pyxidicula*, *A. idahoensis alta*, and *A. primæva* were included with the specimens representing *A. curvata* in this reference to *A. gemma*, but only the last two were figured; *A. idahoensis alta*, Pl. LXVII, figs. 5 and 5a, and *A. primæva*, Pl. LXVII, figs. 5c, 5d, and 5e.)

Acrotreta gemma HALL and CLARKE (in part) [not BILLINGS], 1892, Nat. Hist. New York, Paleontology, vol. 8, pt. 1, p. 102, fig. 55 (not figs. 56 and 57; see below). (Mentioned in the text and fig. 55 copied from Walcott, 1884b, Pl. I, fig. 1d. The specimens represented by figs. 56 and 57 are referred in this monograph to *Acrotreta idahoensis alta*.)

Acrotreta gemma WALCOTT (in part) [not BILLINGS], 1899, Mon. U. S. Geol. Survey, vol. 32, pt. 2, p. 449, Pl. LXII, fig. 2e (not figs. 2, 2a-d; see below). (Fig. 2e is a copy of Walcott, 1884b, Pl. I, fig. 1d. Specimens now referred to *Acrotreta attenuata*, *A. pyxidicula*, *A. idahoensis alta*, and *A. primæva* were included with the specimens representing *A. curvata* when this description of *A. gemma* was written, but only the last two were figured: *A. idahoensis alta*, Pl. LXII, figs. 2a and 2c, and *A. primæva*, Pl. LXII, figs. 2, 2b, and 2d.)

Acrotreta curvata WALCOTT, 1902, Proc. U. S. Nat. Mus., vol. 25, p. 584. (Characterized essentially as below as a new species.)

This is a clearly defined species and all that is known of it, with the exception of the very fine concentric surface striæ, can be illustrated. It belongs with *Acrotreta idahoensis* Walcott and other species with a broad false area. It differs from described species in the incurved apex of the ventral valve, the strong sinus of the dorsal valve, and the general aspect of the two valves.

This form owes its specific name to the fact that the apex of the ventral valve is strongly incurved.

FORMATION AND LOCALITY.—**Passage beds** between the Upper Cambrian and the Ordovician: (203a) *Limestones at base of Pogonip limestone, in the spur on Hamburg Ridge extending out southwest from Wood Cone, Eureka district* [Hague, 1892, Atlas], Eureka County, Nevada.

Upper Cambrian: (12p) About 225 feet (69 m.) above the igneous rocks in the limestones of the Reagan sandstone, at the northwest extremity of the Arbuckle Mountains, about 4 miles (6.4 km.) east of Homer, Carter County, Oklahoma.

ACROTRETA DEFINITA Walcott.

Plate LXIV, figures 2, 2a-g, 3, 3a-b.

Acrotreta definita WALCOTT, 1902, Proc. U. S. Nat. Mus., vol. 25, pp. 584-585. (Described essentially as below as a new species.)

For exterior outline, form, and convexity of the valve, the student is referred to the illustrations (Pl. LXIV). It is to be noted that the false pedicle groove is very distinct and also broader than that of *Acrotreta attenuata* Meek. The interior of the ventral valve is beautifully shown by casts. One of these (fig. 2c) shows the strong vascular sinuses, cardinal scars, cast of apical callosity, and, just in front of the latter, two slight tubercles, which may be the cast of depressions corresponding to the foraminal pits of *Acrothele*. The cast of the dorsal valve is also very instructive in showing the area, cardinal scars, median ridge, and central scars.

Observations.—This large fine species differs from its nearest ally, *Acrotreta idahoensis* Walcott, in the false area and the details of the arrangement of the vascular markings and muscle scars of the interior of the valves. The Idaho shells occur in a dark argillaceous shale and were collected by R. S. Spence, of Evanston, Wyoming. The Eureka (Nevada) specimens (Pl. LXIV, figs. 3, 3a-b) are from a shaly limestone.

Acrotreta depressa (Pl. LXVI, figs. 8, 8a-c) occurs at about the same stratigraphic horizon, but it has, when uncompressed, a more elevated and sharper apex.

FORMATION AND LOCALITY.—**Middle Cambrian:** (55) Shaly limestone at the top of the Eldorado limestone [Walcott, 1908f, p. 184], east slope of Prospect Mountain, in New York Canyon, Eureka district [Hague, 1892, Atlas]; and (57) shaly limestone of the Eldorado limestone [Walcott, 1908f, p. 184], at the 700-foot (213.4 m.) level of the Richmond mine, Ruby Hill [Hague, 1892, p. 43, and Pl. I, opposite p. 116]; both in Eureka County, Nevada.

(55c and 163)^a *Spence shale member of the Ute limestone* [Walcott, 1908a, p. 8], about 50 feet (15.2 m.) above the Brigham quartzite and 2,755 feet (839.7 m.) below the Upper Cambrian, in a ravine running up into Danish Flat from Mill Canyon, about 6 miles (9.6 km.) west-southwest of Liberty, and 15 miles (24.2 km.) west of Montpelier, Bear Lake County, Idaho.

(40) Shale about 375 feet (115 m.) above the unconformable base of the Cambrian, in divide at the head of Jackson Creek (locally known as Sheep Creek), a creek flowing into Jackson Lake about 0.5 mile (0.8 km.) south of its northwestern corner, Teton Mountains, Grand Teton quadrangle (U. S. Geol. Survey), Uinta County, Wyoming.

ACROTRETA DEPRESSA (Walcott).

Plate LXVI, figures 8, 8a-c.

Acrotreta gemma depressa WALCOTT, 1889, Proc. U. S. Nat. Mus. for 1888, vol. 11, pp. 441-442. (Reason given for separation as a new variety.)

Linnarssonvia sagittalis WALCOTT, 1889, idem, p. 442. (Mentioned.)

Acrotreta gemma depressa Walcott, MATTHEW, 1902, Trans. Roy. Soc. Canada for 1902, 2d ser., vol. 8, sec. 4, No. 3, p. 109. (Copies Walcott, 1889c, p. 441, and proposes the species *A. depressa*.)

Acrotreta depressa WALCOTT, 1908, Canadian Alpine Journal, vol. 1, No. 2, p. 245, Pl. I, figs. 3, 3a-c. (No text reference. Figs. 3, 3a-c are copied in this monograph, Pl. LXVI, figs. 8c, 8c', 8a, and 8, respectively.)

A group of depressed ventral valves in an arenaceous argillaceous shale led me [1889c, p. 441] to distinguish the shell as a variety of *Acrotreta gemma* Billings. Material received since 1889, from a black and finer shale, shows an elevated ventral valve much like that of *A. idahoensis alta* Walcott, but at present I am unable to decide that the typical form of

^a 163 is the type locality.

A. depressa (figs. 8 and 8') is the same as the elevated ventral valve represented by figure 8c, or that the latter is *A. idahoensis alta*; neither form should be referred to *A. gemma*. *A. definita* (Pl. LXIV, figs. 2, 2a-g) occurs at the same relative stratigraphic horizon as this species and it is about the same size. It differs in having a lower, less elevated, and less pointed apex on the ventral valve.

This form owes its specific name to the fact that its ventral valve is depressed.

FORMATION AND LOCALITY.—Middle Cambrian: (14s) About 2,300 feet (701 m.) above the Lower Cambrian and 2,700 feet (823 m.) below the Upper Cambrian in the Ogygopsis zone of the Stephen formation [Walcott, 1908f, p. 210], at the great "fossil bed," on the northwest slope of Mount Stephen; (57f) about 2,200 feet (670.6 m.) above the Lower Cambrian and 2,800 feet (853.4 m.) below the Upper Cambrian in the limestone forming 1 of the Stephen formation [Walcott, 1908f, p. 209], about 0.5 mile (0.8 km.) east of the great "fossil bed" on Mount Stephen; (58j) about 1,900 feet (579 m.) above the Lower Cambrian and 3,100 feet (945 m.) below the Upper Cambrian, near the base of the limestone forming 2 of the Stephen formation [Walcott, 1908c, p. 238(7)], on the east side of Mount Stephen about 3,000 feet (914 m.) above the Canadian Pacific Railway track; and (58r) about 1,800 feet (548.6 m.) above the Lower Cambrian and 3,200 feet (975.4 m.) below the Upper Cambrian, in the limestones forming 2 of the Stephen formation [Walcott, 1908f, p. 211], in the amphitheater between Mounts Stephen and Dennis; all near Field on the Canadian Pacific Railway, British Columbia, Canada.

ACROTRETA EGGEGRUNDENSIS Wiman.

Plate LXX, figures 2a-d.

Acrotreta eggegrundensis WIMAN, 1902, Bull. Geol. Inst. Univ. Upsala, vol. 6, pt. 1, No. 11, p. 55, Pl. II, figs. 23-29. (Described in German as a new species. The two specimens represented by figs. 29, 27, and 26, and fig. 24 are redrawn in this monograph, Pl. LXX, figs. 2a-c and 2d, respectively.)
Acrotreta eggegrundensis Wiman, WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 299-300. (Characterized as below.)

This species is of a characteristic Middle Cambrian type of *Acrotreta* represented in America by *A. idahoensis* Walcott and *A. kutorgai* Walcott. The surface is marked by unusually strong lines and ridges of growth and the false area is well defined. It is quite distinct from other species of the genus in European formations.

Carl Wiman [1902, p. 51] refers this species to the *Olenellus* sandstone series. The boulder containing it also carried *Aparchites? anderssoni*, *Hipponicharion matthewi*, *Obolus* (*Westonia*) *bottnicus*, *Kutorgina?*, *Torellella laevigata*, and fragments referred to *Olenellus*. This fauna is essentially Middle Cambrian in its facies, and unless the fragments referred to *Olenellus* are indisputably of that genus, I am inclined to refer the boulder and its contained fossils to the Middle Cambrian. The fact that *Obolus* (*Westonia*) *bottnicus* is nearly identical with *O.* (*W.*) *finlandensis* of the Middle Cambrian of Finland also points to the Middle Cambrian age of the fauna.

The specific name is derived from Eggegrund Island, the type locality.

FORMATION AND LOCALITY.—Middle? Cambrian: (311) Drift boulder of coarse-grained, somewhat friable, glauconitic sandstone, No. 3 [Wiman, 1902, p. 57], on Eggegrund Island, about 25 miles (40 km.) northeast of Gefle, Province of Gefleborg; and (311a) drift boulder of glauconitic sandstone [Wiman, 1902, p. 57], at Norrskedika, a little northwest of Östhammar, Province of Stockholm; both in Sweden.

(311d) Drift boulder of glauconitic sandstone [Wiman, 1902, p. 57], south of Lumparströmmen, Åland Island, Finland, Russia.

ACROTRETA EMMONSI Walcott.

Plate LXV, figure 6.

Acrotreta emmonsi WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 300. (Characterized as below as a new species.)

Only the interiors of the two valves of this species are known. The one illustrated shows the distinct character of the vascular markings and muscle scars. The only shell with which it can be compared is the dorsal valve of *Acrotreta idahoensis* Walcott (Pl. LXV, figs. 1f, 1g). This shell resembles *Obolella*, but its corneous test, cardinal muscle scars, and absence of area of the *Obolella* type prevent a reference to that genus. Fragments of *Olenellus* occur in the layer of limestone from which the specimens were obtained.

The specific name is given in memory of Dr. Ebenezer Emmons, who studied and wrote of the Bald Mountain section.

FORMATION AND LOCALITY.—Lower Cambrian: (35a) *Shaly limestone on the west slope of the summit of Bald Mountain, 3 miles (4.8 km.) north-northwest of Greenwich, Schuylerville quadrangle (U. S. Geol. Survey); and (38a) limestone 2 miles (3.2 km.) south of North Granville, on the road which turns south from the road running between that village and Truthville, 4 miles (6.4 km.) west-northwest of Granville, Fort Ann quadrangle (U. S. Geol. Survey); both in Washington County, New York.*

ACROTRETA GEMMA Billings.

Plate LXVI, figures 1, 1a-b.

Acrotreta gemma BILLINGS, 1865, Geol. Survey Canada, Paleozoic Fossils, vol. 1, pp. 216-217, figs. 201a-f. (Described as below as a new species. The specimens represented by figs. 201b, d, e, and f are redrawn in this monograph, Pl. LXVI, figs. 1, 1a-b, respectively.)

Not *Acrotreta gemma* WALCOTT [1884b, p. 17; 1886b, p. 98; 1891a, p. 608; or 1899, p. 449]. (The specimens referred to *Acrotreta gemma* Billings in the references mentioned have been referred in this monograph to *Acrotreta attenuata*, *A. curvata*, *A. idahoensis alta*, *A. primæva*, and *A. pyxidicula*, which see.)

The original description by Billings follows:

Shell very small, about 1 line in diameter; one valve nearly flat and the other acutely conical. Dorsal valve very gently convex, nearly circular; sides and front margin uniformly rounded; posterior margin very obtusely angulated at the beak, on each side of which a portion of the cardinal edge, equal to one-fourth of the whole width of the shell, is nearly straight; umbo very small; beak apparently depressed to the hinge line and not projecting beyond it; cardinal angles compressed, broadly rounded; a wide, shallow, mesial sinus extends from the front margin about half-way to the beak; elsewhere the valve is gently convex or nearly flat.

Ventral valve acutely conical, with a flat triangular area which is perpendicular to the plane of the lateral margin, its base half the width of the whole shell. In the apex of this valve there is a minute circular aperture, and in one specimen a dark line extends from it down the middle of the area, which appears to represent the foraminal groove of this genus; but in two other specimens of the ventral valve, with the area well preserved, there is no indication of a groove. Surface with very fine concentric striae.

Width of dorsal valve about 1 line; length about eight-ninths of a line. The height of the ventral valve is about 1 line.

The form of this species is very like that of *A. subconica* Kutorga, but that species is twice the size of this and has the area distinctly grooved.

Observations.—By the courtesy of Prof. J. F. Whiteaves, of the Geological Survey of Canada, I have had the opportunity of studying the type material of this species. Nine specimens of the ventral valve were received, but none of the dorsal valve, as they could not be found. One specimen in a dove-colored limestone appears to belong to a distinct species, which I have named *Acrotreta ovalis*. The remaining specimens show some variation in the angle of slope of the sides of the ventral valve, but four of them are similar to the form illustrated by Billings [1865a, p. 216].

The broad false area, with a scarcely perceptible impression of the path of advance of the pseudodeltidium, is clearly shown in one of the specimens, and faintly in others. Two shells have the apex broken off so as to expose the cast of a minute apical callosity and a small portion of the side of the cast of the main vascular sinus (Pl. LXVI, fig. 1b).

Acrotreta gemma belongs to the *A. subconica* Kutorga group of the genus, having a high ventral valve and a distinct and broad false area. It differs from *A. subconica* in having a less elevated ventral valve and in the apex being in front of the posterior margin instead of extending over it. *Acrotreta gemma* has no strong specific relations with the forms from the Rocky Mountains that I identified with it. *A. attenuata* Meek has a high ventral valve, but the false area is practically absent, a narrow, deep sulcus taking its place. *A. idahoensis alta* Walcott has the elevation and false area, but differs in the details of the area and the outline of the cross section of the ventral valve. It was this form that led me [1884b, p. 17] to consider that *A. gemma* occurred in Nevada, and with the slight knowledge that I then had of the genus and species a wide variation of form was given to *A. gemma*. As far as now known to me, the species is restricted to the type locality.

FORMATION AND LOCALITY.—Lower Ordovician: (314d [Billings, 1865a, p. 217]) Limestone of Division P of the "Quebec group," 4 miles (6.4 km.) northeast of Portland Creek, Newfoundland.

ACROTRETA GEMMULA Matthew.

Plate LXVI, figures 3, 3a-c; Plate LXXVII, figures 5, 5a-f.

Acrotreta gemmula MATTHEW, 1894, Trans. Roy. Soc. Canada for 1893, 1st ser., vol. 11, sec. 4, No. 8, pp. 87-88, Pl. XVI, figs. 2a-d. (Described as a new species. The specimens represented by figs. 2a and 2b are redrawn in this monograph, Pl. LXVI, figs. 3a and 3b-c, respectively.)

Acrotreta gemmula MATTHEW, 1895, Trans. New York Acad. Sci. for 1894-5, vol. 14, p. 126, Pl. V, figs. 5a-d. (Changes stratigraphic range. Copies figures from preceding reference.)

Acrotreta gemmula MATTHEW, 1903, Geol. Survey Canada, Rept. Cambrian Rocks Cape Breton, p. 97, Pl. III, figs. 4a-d. (Mentioned. Figures copied from Matthew, 1894, Pl. XVI, figs. 2c, 2d, 2a, and 2b, respectively.)

Shell small, nearly circular in outline, with the posterior margin slightly straightened. Height of ventral valve above the posterior margin about one-half the length of the valve. Apex slightly incurved over the false area, which varies from nearly vertical to an appreciable forward slope from the margin. False area with rounded lateral margins and a rather strong median groove that terminates in a sulcus at the margin and begins at a minute foraminal aperture just beneath the apex. The position of the pedicle aperture causes it to open almost directly backward. The dorsal valve is moderately and rather uniformly convex. Surface of shell marked by fine, concentric striæ and lines of growth, and toward the outer margin by very fine, undulating, concentric striæ that give the surface, when examined by a strong lens, the fretted appearance shown on a larger scale on *Obolus* (*Westonia*) *ella* (Hall and Whitfield) and a few species of *Acrotreta*. The size of the shell is about that of *Acrotreta convexa* Walcott, 1.5 to 2 mm. in diameter. The shell appears to have been rather thin, as it is indented by the pressure of the fine grains of sand of the matrix, and often bends rather than breaks when compressed. It is built up of very thin layers or lamellæ that in the dorsal valve form a thickened rim.

The cast of the interior of the ventral valve indicates a small but distinctly marked apical callosity penetrated by a rather strong pedicle tube that is directed backward at an angle of about 45°. A trace of the main vascular sinuses is shown at the anterolateral edges of the apical callosity; the casts of the cardinal scars are rather large for so small a shell. The interior of the dorsal valve is marked by a rather strong median ridge, large cardinal scars, and small central scars. One of the strongly marked characters is the strong outer rim.

This is a very clearly defined species and the oldest of the Acadian representatives of the genus, occurring, as it does, just below the "*Protolenus* fauna." The position of the pedicle aperture is similar to that of many species of *Acrothyle* and is unusual for the genus, and may be of generic or subgeneric importance.

In the collections made by Loper on Dugald Brook this species occurs with *Obolus* (*Palæobolus*) *brettonensis* (Matthew) in beds beneath *Acrothyra proavia* (Matthew). He collected a fine series of this species at the same horizon from which Matthew obtained the types of his "*Acrotreta papillata*" (see *Acrothyra sera* (Matthew), p. 718). I find that when the outer surface of the shell is well preserved it has a slightly fretted or pitted appearance on specimens from Hanford Brook and also Dugald Brook. Those from Dugald Brook show radiating lines when the thin outer layer of the shell is exfoliated. In some layers of rock all the shells are finely pitted, evidently by the fine grains of quartz sand in the matrix being pressed against the shell; in other layers the shells are identical in surface markings and form with those of *A. gemmula* from Hanford Brook.

The interiors of the dorsal valve are not sufficiently well preserved for comparison, but in the ventral valve they are essentially the same. In each locality there is considerable variation in the form and size of the apical callosity.

FORMATION AND LOCALITY.—Middle Cambrian: (301a [Matthew, 1894, p. 88]) *Fine-grained sandstones below the Protolenus-bearing shales and sandstones in Division 1b3 of Matthew on Hanford Brook*; and (301 [Matthew, 1895a, p. 126]) sandstones of Division 1b2 of the "*Protolenus* zone" of Matthew on Hanford Brook; both in St. John County, New Brunswick.

(10p) Sandstone just below the waterfall in Division E2b of Matthew's [1903, p. 21] Etcheminian, Dugald Brook, Indian River; and (10p') sandstone on the small brook on the hill between the bridge over Indian River and McPhees Brook; both in eastern Cape Breton, Nova Scotia, Canada.

ACROTRETA GRACIA Walcott

Plate LXVI, figures 5, 5a-d.

Acrotreta gracia WALCOTT, 1902, Proc. U. S. Nat. Mus., vol. 25, pp. 586-587. (Described and discussed essentially as below as a new species.)

Shell small, slightly transverse; apex of ventral valve about one-third the length of the shell from the posterior margin; height about two-thirds the length of the shell; false area defined by the sharp rounding of the cardinal slopes and the transverse posterior margin, which is indented by the strong, broad, median groove extending from the margin to the apex, where it almost comes in contact with the minute apical pedicle opening. Dorsal valve moderately convex with a nearly straight or gently curved posterior margin; beak minute, marginal. Surface of shell marked by fine concentric striæ and lines of growth. Shell strong and built up of thin layers or lamellæ that over the central and anterior portions are more or less oblique to the outer surface layer.

The cast of the ventral valve indicates a small but very clearly marked apical callosity; rather small cardinal scars and main vascular sinuses. The false area is narrow and broken midway by a rather wide, slightly arching false deltidium. The cast of the interior of the dorsal valve shows a broad, low, median ridge extending to about the anterior third of the length of the valve, large cardinal muscle scars, and small main vascular sinuses that arch inward after passing the central scars, and then outward.

Observations.—This species is distinguished by the strong shell, broad median ridge of the dorsal valve, and deep median groove of the false area of the ventral valve. The light color of the shell may be owing to the character of the limestone in which it is preserved, or it may be that it is a little more calcareous than other species of the genus.

The *Acrotreta* which Matthew [1897b, p. 169] describes and illustrates from the Hastings Cove locality ("*Linnarssonina belti magna*") is characterized by a narrow median ridge in the dorsal valve and other characters not present in *A. gracia*. In the *Paradoxides* zone on Hanford Brook I found numerous examples of a species of *Acrotreta* that appears to be identical with the form described by Matthew [1897b, p. 169] and have referred it as a variety (*magna*) of *Acrotreta sagittalis* (Salter) (p. 706).

FORMATION AND LOCALITY.—Middle Cambrian: (2s) Limestone in upper part of *Paradoxides* zone, Hastings Cove [Matthew, 1898b, p. 38], on Kennebecasis Bay, 0.5 mile (0.8 km.) northeast of Torryburn, on the Intercolonial Railway, northeast of St. John, St. John County, New Brunswick.

ACROTRETA IDAHOENSIS Walcott.

Plate LXV, figures 1, 1a-i; Plate LXVIII, figures 2, 2a-g.

Acrotreta attenuata MEEK (in part), 1873, Sixth Ann. Rept. U. S. Geol. and Geog. Survey Terr. for 1872, p. 463, footnote. (Among the specimens which Meek listed as *A. subconica* and for which he proposed the name *A. attenuata* in a footnote are specimens which are now referred to *A. idahoensis*. See also *A. attenuata* and *A. attenuata* var.)

Not *Acrotreta subconica* KUTORGA, 1848, Verhandl. Russ.-kais. min. Gesell. St. Petersburg for 1847, No. 12, p. 275. (Referred in this monograph to *Acrotreta subconica*.)

Acrotreta idahoensis WALCOTT, 1902, Proc. U. S. Nat. Mus., vol. 25, p. 587. (Described essentially as below as a new species.)

The general outline, form, and convexity of the two valves are so fully shown by the illustrations that detailed descriptions will not be given. The material for illustrating the interior of the ventral valve is limited, but one cast shows the position of the base of the cast of the foraminal tube, and the large, main vascular sinuses (Pl. LXV, fig. 1d). An interior of a dorsal valve and the accompanying cast (Pl. LXV, figs. 1f, 1g) present characters rarely seen in this genus. The vascular canals arch out beyond the central muscle scars, and then bend in toward the median ridge, and again obliquely outward to form the outer limit of a smooth, polished, lanceolate-shaped surface that extends obliquely outward from the median ridge. The line that extends from in front of the cardinal scars forward, subparallel to the margin of the shell, and then bends abruptly in and forward is apparently the outer boundary of a very broad,

shallow, vascular sinus. Something of this same character occurs in the dorsal valve of *Obolus (Lingulobolus) spissus* (Billings) (Pl. XVI, figs. 2, 2d). The cardinal scars are small and situated close to the narrow area. Another cast of the interior (fig. 1e) shows the central scars distinctly; also the presence of a thickening of the shell in the vicinity of the cardinal scars. The median ridge is smaller and shorter than in Plate LXV, figure 1g.

Observations.—The external characters of this species suggest *Acrotreta curvata* Walcott, but the elevation and curvature of the ventral valve are not the same and the interior of the dorsal valve is very distinct in its specific characters. There are no interiors of the form from the Black Hills, but the external characters appear to be the same. These include the broad false area, with its slightly marked groove, the position of the apex, and the curvature of the false area.

Acrotreta idahoensis has been found in the Dunderberg shale of the Eureka district, Nevada, and it extends up also to the base of the Pogonip limestone. The horizon is higher than that of the type specimen, but the shells from the higher and lower horizons appear to be identical.

FORMATION AND LOCALITY.—**Lower Ordovician:** (201a) Pogonip limestone, east slope of the ridge east of Hamburg Ridge; and (202) Pogonip limestone on the summit of the ridge directly southeast of the Jackson mine, north-west of Shadow Canyon; both in the Eureka district [Hague, 1892, Atlas], Eureka County, Nevada.

Upper Cambrian: (61) Limestone in the Dunderberg shale [Walcott, 1908f, p. 184], a little south of the Hamburg mine, Eureka district [Hague, 1892, Atlas], Eureka County; and (313) limestone 0.75 mile (1.2 km.) east-northeast of McGill post office, White Pine County; both in Nevada.

(15d) Thin-bedded blue limestone near Cave Spring, on the east side of the Fish Spring Range, about 4 miles (6.4 km.) south of the J. J. Thomas ranch, Juab County; and (30h) about 350 feet (106.7 m.) above the Middle Cambrian and 2,950 feet (899.2 m.) below the top of the Upper Cambrian, near the base of the arenaceous limestones forming 2a of the Orr formation [Walcott, 1908f, p. 177], on Orr Ridge, about 5 miles (8 km.) south of Marjum Pass, House Range [Walcott, 1908f, Pl. XIII], Millard County; both in Utah.

(5c and 54t) Limestones of the St. Charles formation [Walcott, 1908a, p. 6], about 250 feet (76 m.) above the Middle Cambrian; and (54u) limestones of the St. Charles formation about 100 feet (30.2 m.) above the Middle Cambrian; both on the north side of Twomile Canyon near its mouth, 2 miles (3.2 km.) southeast of Malade, Oneida County, Idaho.

(56g) Limestone of the St. Charles formation [Walcott, 1908a, p. 6], in the valley of the stream which flows into Mill Canyon from the west, about 6 miles (9.6 km.) west-southwest of Liberty and 15 miles (24.2 km.) west of Montpelier, Bear Lake County, Idaho.

Middle Cambrian: (88a) Limestone about 100 feet (30.5 m.) above the quartzitic sandstone at the base of the Cambrian, in the northern suburbs of Deadwood; and (165) limestone on the east side of the valley, in railroad cut about 1 mile (1.6 km.) below the main part of Deadwood; both in the Black Hills, South Dakota.

(302a) Limestones at several places on the south side of the Gallatin Valley, Gallatin County, Montana.

(302b) Limestones near Crowfoot Ridge, Gallatin quadrangle (U. S. Geol. Survey), Yellowstone National Park, Wyoming.

(59g) Limestones immediately overlying the Spence shale member of the Ute limestone [Walcott, 1908a, p. 8], in a saddle north of the creek which flows into Mill Canyon from the west, about 5 miles (8 km.) west-southwest of Liberty and 15 miles (24.2 km.) west of Liberty, Bear Lake County, Idaho.

(11o) About 2,750 feet (838.2 m.) above the Lower Cambrian and 1,650 feet (502.9 m.) below the Upper Cambrian, at the base of 1a of the Marjum limestone [Walcott, 1908f, p. 179], about 4 miles (6.4 km.) southeast of Antelope Springs, in the spur at the junction of the Deseret and Swasey Spring roads [Walcott, 1908f, Pl. XIII], House Range, Millard County, Utah.

ACROTRETA cf. IDAHOENSIS.

This species is represented by a single specimen of a somewhat imperfect ventral valve. It is larger than the average shells of *Acrotreta idahoensis* Walcott, and appears to have had a more incurved apex. The exterior layer is also duller and less distinctly striated than most specimens of the latter species. The shell is built up of numerous thin layers or lamellæ, more or less oblique to the outer surface; the lamellæ are marked by numerous fine radiating striæ and a few concentric striæ. The general impression given by the shell is that it is an old shell which has thickened by growth and become more robust and incurved than is usual in the species with which it is compared.

FORMATION AND LOCALITY.—**Middle Cambrian:** (7j) Limestones at the north end of the Quinn Canyon Range, 1 mile (1.6 km.) northwest of the Italian Ranch foothills, Nye County, Nevada.

ACROTRETA IDAHOENSIS ALTA Walcott.

Plate LXV, figures 4, 4a-b.

- Acrotreta gemma* WALCOTT (in part) [not BILLINGS], 1884, Mon. U. S. Geol. Survey, vol. 8, pp. 17-18, Pl. I, figs. 1a and 1b (not figs. 1c-f; see below), and (?) Pl. IX, figs. 9 and 9a (see also below). (Specimens now referred to *Acrotreta attenuata*, *A. pyxidicula*, and *A. curvata* were included with the specimens representing *A. idahoensis alta* when this description of *A. gemma* was written, *A. curvata* being figured, Pl. I, figs. 1d and 1e. The specimen represented by Pl. I, fig. 1a, is redrawn in this monograph, Pl. LXV, fig. 4a. Fig. 1c represented a specimen of *Acrotreta sabrinæ*; the specimens represented by figs. 1f and 9 and 9a are missing.)
- Acrotreta gemma* WALCOTT (in part) [not BILLINGS], 1891, Tenth Ann. Rept. U. S. Geol. Survey, p. 608, Pl. LXVII, figs. 5 and 5a (not figs. 5b-e; see below). (Figs. 5 and 5a are copied from figs. 1a and 1b of preceding reference. Specimens now referred to *Acrotreta attenuata*, *A. pyxidicula*, *A. curvata*, and *A. primæva* were included with the specimens representing *A. idahoensis alta* in this reference to *A. gemma*, but only the last two were figured: *A. curvata*, Pl. LXVII, fig. 5b, and *A. primæva*, Pl. LXVII, figs. 5c, 5d, and 5e.)
- Acrotreta gemma* Walcott, HALL and CLARKE (in part) [not BILLINGS], 1892, Nat. Hist. New York, Paleontology, vol. 8, pt. 1, p. 102, figs. 56 and 57 (not fig. 55). (Mentioned in the text, and figures copied from Walcott, 1884b, Pl. I, figs. 1a and 1b. The specimen represented by fig. 55 is referred in this monograph to *Acrotreta curvata*.)
- Acrotreta gemma* WALCOTT (in part) [not BILLINGS], 1899, Mon. U. S. Geol. Survey, vol. 32, pt. 2, p. 449, Pl. LXII, figs. 2a and 2c (not figs. 2, 2b, 2d, and 2e; see below). (Figs. 2a and 2c are copied from Walcott, 1884b, Pl. I, figs. 1a and 1b, respectively. Specimens now referred to *Acrotreta attenuata*, *A. pyxidicula*, *A. curvata*, and *A. primæva* were included with the specimens representing *A. idahoensis alta* when this description of *A. gemma* was written, but only the last two were figured: *A. curvata*, Pl. LXII, figs. 2c, and *A. primæva*, Pl. LXII, figs. 2, 2b, and 2d.)
- Acrotreta idahoensis alta* WALCOTT, 1902, Proc. U. S. Nat. Mus., vol. 25, p. 588. (Characterized essentially as below as a new variety.)

This is one of the forms that I included with *Acrotreta gemma* Billings in the report on the Paleontology of the Eureka district, Nevada [1884b, p. 17]. It has the broad false area of *A. idahoensis* Walcott, but the ventral valve is more elevated and the apex does not overhang the false area. From *A. attenuata* Meek it differs in having a broad false area.

A form indistinguishable from *Acrotreta idahoensis alta* occurs in the Dunderberg shale of the Eureka district section of Nevada. The horizon is higher than that of the type specimen, but there appears to be no way of distinguishing between the type and the Dunderberg shale specimens.

A similar but smaller form extends up through from the Dunderberg shale into the arenaceous and calcareous shales at the base of the Pogonip limestone, where fossils of the Ordovician fauna occur.

This form owes its varietal name to its high ventral valve.

FORMATION AND LOCALITY.—**Lower Ordovician:** (63) At base of Pogonip limestone, northeast of Adams Hill, Eureka district [Hague, 1892, Atlas], Eureka County, Nevada.

Passage beds between the Upper Cambrian and the Ordovician: (201) Arenaceous Pogonip limestone on east slope of ridge east of Hamburg Ridge; and (206a) sandy limestone on Hoosac Mountain; both in the Eureka district [Hague, 1892, Atlas], Eureka County, Nevada.

Upper Cambrian: (61) Limestone in the Dunderberg shale [Walcott, 1908f, p. 184], a little south of the Hamburg mine; and (65) limestone on the east side of Sierra Canyon, opposite Pinnacle Peak; both in the Eureka district [Hague, 1892, Atlas], Eureka County, Nevada.

(54f) 150 feet (45.7 m.) above the Middle Cambrian and 1,075 feet (327.7 m.) below the top of the Upper Cambrian in light-gray sandstone forming No. 4 of the St. Charles formation [Walcott, 1908f, p. 193], in Blacksmith Fork Canyon about 10 miles (16.1 km.) east of Hyrum, Cache County; (34q) shales about 3,800 feet (1,158.2 m.) above the Brigham quartzite [Walcott, 1908a, p. 8], in Wasatch Canyon, east of Lakeview ranch, about 5 miles (8 km.) north of Brigham, Boxelder County; and (15d) thin-bedded blue limestone near Cave Spring on the east side of the Fish Spring Range, about 4 miles (6.4 km.) south of the J. J. Thomas ranch, Juab County; all in Utah.

Middle? Cambrian: (33n) Limestone pebbles, west front of the Pavant Mountains, at the mouth of Crow Creek, about 4 miles (6.4 km.) east of Fillmore, Millard County, Utah.

Middle Cambrian: (58) *Shaly limestone in upper beds of Secret Canyon shale, east side of New York and Secret canyons, Eureka district* [Hague, 1892, Atlas], Eureka County, Nevada.

(7i) Limestone just west of the summit on the road east of Schellbourne; and (313b) limestones 3 miles (4.8 km.) north-northeast of Schellbourne; both in the Schell Creek Range, White Pine County, Nevada.

(302w) Limestone at Madison Mountain, Montana.

ACROTRETA IDAHOENSIS SULCATA Walcott.

Plate LXV, figure 5.

Acrotreta idahoensis sulcata WALCOTT, 1902, Proc. U. S. Nat. Mus., vol. 25, p. 588. (Characterized as below as a new variety.)

This strongly marked ventral valve is associated with the variety *alta*, but in its rounded posterior side and strong median groove it is quite distinct. The apex is broken off so as to show the cast of a small apical callosity and the base of a minute foraminal tube.

This form owes its varietal name to the fact that it possesses a sulcate ventral valve.

FORMATION AND LOCALITY.—Upper Cambrian: (30h) About 350 feet (106.7 m.) above the Middle Cambrian and 2,950 (899.2 m.) below the top of the Upper Cambrian, near the base of the arenaceous limestones forming 2a of the Orr formation [Walcott, 1908f, p. 177], on Orr Ridge, about 5 miles (8 km.) south of Marjum Pass, House Range [Walcott, 1908f, Pl. XIII], Millard County, Utah.

(54t) Limestone of the St. Charles formation [Walcott, 1908a, p. 6], about 250 feet (76 m.) above the Middle Cambrian, on the north side of Twomile Canyon, near its mouth, 2 miles (3.2 km.) southeast of Malade, Oneida County, Idaho.

Middle Cambrian: (54s) Dark blue-gray Langston limestone [Walcott, 1908f, p. 198], just above the Cambrian quartzitic sandstones, north side of Twomile Canyon, near its mouth, 2 miles (3.2 km.) southeast of Malade, Oneida County; (55e) Spence shale member of the Ute limestone [Walcott, 1908a, p. 8], about 50 feet (15.2 m.) above the Brigham quartzite and 2,755 feet (839.7 m.) below the Upper Cambrian, in a ravine running up into Danish Flat from Mill Canyon, about 6 miles (9.6 km.) west-southwest of Liberty and 15 miles (24.2 km.) west of Montpelier, Bear Lake County; and (322a) *Langston limestone near Paris, Bear Lake County*; all in Idaho.

ACROTRETA INCHOANS (Barrande).

Plate XV, figures 7, 7a.

Lingula inchoans BARRANDE, 1868, Faune silurienne des environs de Hof, en Bavière, p. 102, figs. 74 and 75. (Described in French as a new species; see below for translation. Figs. 74 and 75 are reproduced in this monograph, Pl. XV, figs. 7 and 7a, respectively.)

Lingula inchoans BARRANDE, 1868, Neues Jahrb. für Mineralogie for 1868, p. 692, unnumbered plate, figs. 74 and 75. (Copy of preceding reference.)

Acrothele inchoans (Barrande), POMPECKJ, 1896, Tremadoc Fossilien bei Hof, p. 3. (Discussed in German.)

Acrothele inchoans (Barrande), MATTHEW, 1902, Bull. Nat. Hist. Soc. New Brunswick, vol. 4, pt. 5, No. 20, p. 404. (Mentioned.)

Acrothele inchoans (Barrande), MATTHEW, 1903, Geol. Survey Canada, Rept. Cambrian Rocks Cape Breton, p. 103. (Copy of preceding reference.)

The original description by Barrande follows:

Under this name we unite several very small shells, rounded in appearance, but more or less elongated, which, however, might represent merely the youthful form of another species. These very flat shells show one or two concentric grooves at the external contour. The one which is represented in figure 74 [Pl. XV, fig. 7, of this work] has, moreover, in the middle a faint longitudinal groove which extends nearly throughout its length.

Dimensions: Length, 2 mm.; breadth, 3.2 mm. on the specimen in figure 74 [Pl. XV, fig. 7, of this work].

Observations.—Pompeckj wrote me that he had concluded that this species was an *Acrotreta* and not a *Lingula*. The illustrations and descriptions of Barrande suggest that the specimens represent the compressed dorsal valves of *Acrotreta*.

Matthew [1902a, p. 404] places this species under *Acrothele*, but with only the figure given by Barrande I prefer to accept Pompeckj's provisional reference to *Acrotreta*.

FORMATION AND LOCALITY.—Passage beds between the Upper Cambrian and the Ordovician: (303e [Barrande, 1868a, p. 102]) *Dark argillaceous shale in the suburbs of Hof*; and (303f [Pompeckj, 1896a, pp. 7 and 8]) railway cut near Schellenberg, a little distance back of the railway station at Neuhoif, near Hof; both in Bavaria, Germany.

ACROTRETA INFLATA (Matthew).

Plate LXXVI, figures 1, 1a-k, 2, 2a.

Lingulella? inflata MATTHEW, 1886, Trans. Roy. Soc. Canada for 1885, 1st ser., vol. 3, sec. 4, No. 4, p. 33, Pl. V, figs. 7 and 7a. (Discussed as a new species. The specimen represented by figs. 7 and 7a is redrawn in this monograph, Pl. LXXVI, fig. 2.)

Lingulella? inflata MATTHEW, 1895, Trans. New York Acad. Sci. for 1894-95, vol. 14, p. 127, Pl. V, figs. 3a-b. (Mentioned. Figures copied from preceding reference.)

Lingulella? inflata ovalis MATTHEW, 1895, Trans. New York Acad. Sci. for 1894-95, vol. 14, p. 127, Pl. V, figs. 4a-c. (Described and discussed as a new variety. The specimen represented by figs. 4a-c is redrawn in this monograph, Pl. LXXVI, fig. 2a.)

Lingulella? inflata MATTHEW, 1898, Trans. Roy. Soc. Canada for 1898, 2d ser., vol. 4, sec. 4, No. 2, p. 128. (Mentioned.)

Acrothyra? inflata MATTHEW, 1901, Bull. Nat. Hist. Soc. New Brunswick, vol. 4, pt. 4, No. 19, p. 304. (Merely suggests change in generic reference.)

Lingulella (Acrothyra?) inflata MATTHEW, 1902, idem, vol. 4, pt. 5, No. 20, p. 390. (Mentioned.)

Acrotreta inflata (Matthew), WALCOTT, 1902, Proc. U. S. Nat. Mus., vol. 25, pp. 588-589. (Described essentially as below.)

Shell subcircular to transversely broad oval. Ventral valve subconical, with the apex directed backward and usually on a line with the posterior margin, or extending beyond it (Pl. LXXVI, figs. 1' and 1a'), but it may be anterior to it (Pl. LXXVI, figs. 1b' and 1d'); false area slightly defined by the abrupt curvature of the cardinal slopes, median line depressed, narrow, the two sides of the false area incurving to form it (Pl. LXXVI, fig. 1g); pedicle aperture longitudinally oval and slightly truncating the apex. Dorsal valve gently convex, with a minute marginal beak. Surface of shell marked by concentric striae and growth lines, and fine, irregular, wavy striae that inosculate more or less, giving the surface a fretted appearance under a strong lens. The inner surface is marked by concentric lines and rather strong radiating lines. The shell is built up of a thin outer ornamented surface and several thin inner layers or lamellæ. The average length of the ventral valve is 4 mm. and the width 3 to 3.5 mm. The dorsal valves are usually wider than long. Casts of the interior of the ventral valve show strong cardinal scars, a strong apical callosity, and rather weakly developed main vascular sinuses. The apical callosity varies in size and in form from elongate oval (Pl. LXXVI, fig. 1b) to subcircular (fig. 1f). The cast of the interior of the dorsal valve shows large cardinal muscle scars, and a broad, short median ridge posteriorly that extends beyond the center of the valve.

Observations.—This species appears to be a true *Acrotreta* with the apical callosity elongated by the elongation of the ventral valve. The dorsal valve is more convex than in most species of *Acrotreta*, which gives a stronger relief to the ridges on the cast between the cardinal scars and the median ridge. The posterior view (Pl. LXXVI, fig. 1k') should be compared with the same view of the dorsal valve of *Acrotreta sagittalis* (Salter) and its varieties (Pl. LXXI, figs. 11', 1m', and 3g''; and Pl. LXXII, figs. 1e' and 1f'). The fretted surface is of the same type as that of several other species of the genus.

Matthew had very little material when he described the species [1886, p. 33]; subsequently [1895a, p. 127] he created the variety *ovalis* from a more elongated ventral valve. In the collection made for the United States National Museum by Loper, there are a number of ventral and dorsal valves. The range of variation in outline appears to cover the variety *ovalis*. Some are more transverse than the original type of the species and others nearly as elongate as the variety *ovalis*. I have therefore considered the variety as within the original species. Some of the shells show elongation and others are broadened by distortion.

Matthew [1895a, p. 127] called attention to the resemblance of this species to *Linnarssonina* and *Acrotreta*, and when describing the genus *Acrothyra* suggested [1901b, p. 304] that it might belong to that genus. It appears, however, to be a true *Acrotreta*. A series of specimens, supplemented by the types and a number of ventral valves received from Doctor Matthew which he had [1895a, p. 126] provisionally identified as "*Acrotreta gemma* Billings?" show a rather remarkable variation in outline and position of the apex of the ventral valve. This is illustrated by the figures on Plate LXXVI, also by a number of specimens not illustrated. The narrow forms, var. *ovalis* Matthew, have the apex extended beyond the posterior margin, and in the broad forms the apex is above or in advance of the posterior margin, but if the shells are compressed vertically the apex may be pushed out over the false area whether the shell be narrow or broad. I think that in the normal form the false area is vertical or slightly inclined backward.

FORMATION AND LOCALITY.—Middle Cambrian: (2f and 2g)^a Sandstones of Division 1b1 of Matthew's [1895a, p. 108] *Protolenus* zone, Hanford Brook, St. John County, New Brunswick, Canada.

^a The specimens in the United States National Museum collections to which these numbers are assigned were collected at the type locality but later than the type specimens.

ACROTRETA KUTORGAI Walcott.

Text figure 58; Plate LXV, figures 3. 3a-e, 3g-k.

Acrotreta kutorgai WALCOTT (in part), 1902, Proc. U. S. Nat. Mus., vol. 25, pp. 589-590. (Described as a new species, but owing to a different interpretation of the structural characters of the ventral valve the description differs from the one given below. Specimens now referred to *Acrotreta rudis* were included with true representatives of *A. kutorgai* in this description.)

The external characters of the ventral valve are clearly exhibited (Pl. LXV) by figures 3, 3a, and 3d, and what is known of the interior by figures 3b and 3c. Figure 3g is that of a most interesting specimen, as it clearly shows the cast of the cardinal area of the dorsal valve adjusted against the false area and pseudodeltidium of the ventral valve. In 1902 (p. 589) I considered this cast of the cardinal area of the dorsal valve to be the true area and pseudodeltidium of the ventral valve, and figure 3g was drawn to bring out this interpretation.

Figure 58 represents a view into the interior of the cast, showing the cast of the false area and pseudodeltidium of the ventral valve, as well as the cast of the cardinal area of the dorsal valve. The cardinal area of the dorsal valve is well defined in the casts represented by Plate LXV, figures 3h-j. The median ridge of the dorsal valve is as long proportionally as that of *A. bisecta*, and like it varies in length and size in different shells.

FIGURE 58.—*Acrotreta kutorgai* Walcott. View into interior, the specimen being tipped, as shown in the side outline. A vertical view of the same specimen is shown in Plate LXV, figure 3g.

The specimen represented is from Locality 90x, in Coosa Valley, Alabama (U. S. Nat. Mus. Cat. No. 35277a).

The outer surface is marked by fine concentric striæ and lines of growth.

Observations.—This pretty species occurs attached to the surface of siliceous nodules in association with *Olenoides curticei*, *Crepicephalus texanus*, *Acrothele bellula* Walcott, and casts of Medusæ. The outline of the convexity of the valves and the posterior view of the ventral valve is most like that of *A. attenuata* Meek, but the interior markings are quite unlike.

The specific name was given in honor of Kutorga.

FORMATION AND LOCALITY.—**Upper Cambrian:** (361) Shaly limestone in suburb of Attalla, Etowah County, Alabama.

(107o and 107u) Limestones and shales at the base of the Knox dolomite, west of the top of Copper Ridge, near the Southern Railway cut, about 10 miles (16.1 km.) northwest of Knoxville [Keith, 1896b, areal geology sheet], Knox County, Tennessee.

Middle Cambrian: (90b) Conasauga limestone in cut on Louisville and Nashville Railroad, near Woodstock, Bibb County; (90) Conasauga ("Coosa") shale on Edwards farm, near Craigs Mountain, about 10 miles (16.1 km.) southeast of Center, Cherokee County; (140) limestone interbedded in shales near Chepultepec, Blount County; (90x) in and attached to the outer surface of siliceous nodules in the Conasauga ("Coosa") shale, Coosa Valley, Cherokee County; (137) shales on the southeast side of the northeast end of the Cane Creek Mountains, 3 miles (4.8 km.) south of Gadsden, Etowah County; and (139a) limestones on road near Wades Gap, near Chepultepec, Blount County; all in Alabama.

Specimens that are somewhat doubtfully referred to this species occur at the following localities:

Middle Cambrian: (142) Shales just above the *Olenellus* zone, near the railroad, 4.5 miles (7.2 km.) north of Montevallo, Shelby County, Alabama.

(18) Limestone 1 mile (1.6 km.) east of Gap Creek, 13 miles (20.8 km.) S. 75° E. of Knoxville, Knox County, Tennessee.

ACROTRETA LISANI Walcott.

Plate LXVIII, figures 3. 3a-c.

Acrotreta liani WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 300. (Described and discussed as below as a new species. Li San's name was at that time believed to be correctly written as Lian, hence the form of the specific name.)

Shell small, about 1.5 mm. in diameter; outline of aperture subcircular, the posterior side being slightly transverse. Ventral valve conical, with the apex a little in advance of

the posterior margin; false area indefinite, except for a rather strong, shallow furrow that extends from the apex to the margin. The elevation of the valve is about two-thirds its diameter at its aperture. Dorsal valve slightly convex, apex marginal. Surface of shell marked by fine, concentric striæ and lines of growth that on the dorsal valve tend to form low ridges toward the outer margins.

Observations.—This species is the representative of the American *Acrotreta idahoensis sulcata* Walcott. It has the same type of false area, and the ventral valve is of average height.

The specific name is given in recognition of Li San, Mr. Willis's faithful Chinese interpreter.

FORMATION AND LOCALITY.—**Middle Cambrian:** (C22) Changhia limestone in upper oolitic portion [Blackwelder, 1907a, pp. 22 and 33 (part of last list of fossils)], at Changhia, Shantuug, China.

ACROTRETA MARJUMENSIS Walcott.

Plate LXXVIII, figures 2, 2a-d.

Acrotreta marjumensis WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 3, pp. 94-95, Pl. IX, figs. 2 and 2a. (Described and discussed as below as a new species. Figs. 2 and 2a are copied in this monograph, Pl. LXXVIII, figs. 2 and 2c, respectively.)

The general form of this species is much like that of *Acrotreta idahoensis* Walcott. The ventral valve differs in having a more strongly marked and broader false area and in the greater curvature of the apex over the false area. It is also less elevated, or convex, in proportion to the size of the shell. It may also be compared with *A. neboensis* Walcott, from which it differs in being less elevated and in not having a well-indicated false pedicle furrow. The dorsal valve is moderately convex and differs little from the dorsal valve of *A. idahoensis* and *A. neboensis*.

The interior of the dorsal valve shows a narrow median ridge that, at the center and toward the front of the shell, rises as a sharp, rather high, and very narrow ridge. This ridge starts posteriorly from a subtriangular, somewhat elevated area which has a longitudinal furrow crossing it. The cardinal and central muscle scars are very clearly defined; in some cases the central scars are slightly depressed, and in other shells elevated above the general surface of the interior of the shell.

The specific name is derived from Marjum Pass, near the type locality.

FORMATION AND LOCALITY.—**Upper Cambrian:** (33d) Thin-bedded blue limestone at the base of the first high point southwest of the J. J. Thomas ranch, on the east side of the Fish Spring Range, Juab County, Utah.

Middle Cambrian: (11n) About 3,000 feet (914.4 m.) above the Lower Cambrian and 1,400 feet (426.7 m.)¹ below the Upper Cambrian, in the upper part of the limestone forming 1a of the Marjum limestone [Walcott, 1908f, p. 179], in the long cliff 2 miles (3.2 km.) southeast of Marjum Pass, House Range [Walcott, 1908f, Pls. XIII and XV], Millard County, Utah.

ACROTRETA MICROSCOPICA (Shumard).

Plate LXVII, figures 1, 1a-h, 1o, 2, 2a-d.

Discina microscopica SHUMARD, 1861, Am. Jour. Sci., 2d ser., vol. 32, p. 221. (Described as a new species.)

The external outline, form, and convexity of the two valves are so fully illustrated by the figures that I will only call attention to the variation in the outline of the elevation of the ventral valve. In Plate LXVII, figure 1d'', the false area slopes backward instead of forward as in other specimens. The lines of growth show that the growth of the anterior portion of the shell was much more rapid than on the posterior face, thus causing the apex to tip back toward the area, a feature not observed in the other specimens illustrated. The concentric surface striæ are sharp, but very fine. The only interior of a ventral valve found is represented by figures 1o, 1o', and 1o''.

The typical forms from Texas are represented by Plate LXVII, figures 1, 1a-h, and 1o, and what appears to be an identical form from Nevada by figures 2, 2a-d. The latter form shows about the same range of variation in outline and position of the apex of the ventral valve as the typical forms from Texas. This species belongs to the group of forms with a wide false area. It differs from *A. idahoensis* Walcott and *A. curvata* Walcott in the form of the ventral valve.

Acrotreta microscopica has remained without illustration for many years. I made a large collection in Burnet County, Texas, in 1884, which was increased by Cooper Curtice in 1890. We found the little shell in great numbers associated with characteristic Upper Cambrian fossils. In the Eureka district, Nevada, there is a small species of *Acrotreta*, which, so far as can be determined from the material available for study, is identical with the *A. microscopica* as it occurs in the Upper Cambrian limestones of Texas. It has essentially the same range of variation in the form of the ventral valve, and the dorsal valves also appear to be identical. (Compare figs. 1 and 2a (the latter has been broadened by pressure); figs. 1d' and 2'; and the side outlines 1a and 2c; and 1b'' and 2b.) The ventral valves have the same outline and convexity. The outlines of the convexity of figures 1e-g should be more nearly as in figures 1h and 2d and not concavo-convex as shown on the plate.

FORMATION AND LOCALITY.—Upper Cambrian: (67) Sandstone on Tatur Hill, 7 miles (11.2 km.) northwest of Burnet, Burnet County; and (70e) limestone near Morgans Creek, Burnet County; (69) limestone near Honey Creek, Burnet County; (71) limestone in Cold Creek Canyon, Burnet County; (68 and 68e) limestone in Packsaddle Mountain, Llano County; (14b) limestone on Cold Creek at north end of gorge opposite the north end of Sponge Mountain, 2 miles (3.2 km.) south of the San Saba County line, in Llano County; (14g) limestone 1 mile (1.6 km.) west of Cherokee, San Saba County; and (14e) limestone in Bartlett Hollow, 2 miles (3.2 km.) southeast of the mouth of Falls Creek, Burnet quadrangle (U. S. Geol. Survey), Lampasas County; all in Texas.

(12p) About 225 feet (69 m.) above the igneous rocks, in the limestones of the Reagan sandstone, at the northwest extremity of the Arbuckle Mountains, about 4 miles (6.4 km.) east of Homer, Carter County; (12n) limestones of the Reagan sandstone (in the section 7 miles (11.2 km.) north of Springer this horizon is about 240 feet (73 m.) above the porphyry contact and 40 feet (12 m.) below the Arbuckle limestone), NW. $\frac{1}{4}$ sec. 1, T. 2 S., R. 1 E., Ardmore quadrangle, Carter County; (12k) limestones of the Reagan sandstone (in the section 7 miles (11.2 km.) north of Springer this horizon is about 225 feet (69 m.) above the porphyry contact and 55 feet (17 m.) below the Arbuckle limestone), on the west side of Honey Creek, near the southeast corner of sec. 35, T. 1 S., R. 1 E., Ardmore quadrangle (U. S. Geol. Survey), Carter County; and (9r and 9t) about 45 feet (14 m.) and 170 feet (52 m.), respectively, above the porphyry contact in the limestones of the Reagan sandstone, SE. $\frac{1}{4}$ NE. $\frac{1}{4}$ sec. 2, T. 4 N., R. 13 W., 15 miles (24.2 km.) northwest of Fort Sill, Comanche County; all in Oklahoma.

Upper? Cambrian: (8o) Limestone on the slope of the ridge where the range swings around to the northwest, 2 miles (3.2 km.) north of Aurum, Schell Creek Range, White Pine County, Nevada.

Middle Cambrian: (58) Shaly limestones in upper beds of Secret Canyon shale, east side of New York and Secret canyons, Eureka district [Hague, 1892, Atlas], Eureka County, Nevada.

ACROTRETA MICROSCOPICA MISSOURIENSIS Walcott.

Plate LXVII, figures 4, 4a-b.

Acrotreta microscopica missouriensis WALCOTT, 1902, Proc. U. S. Nat. Mus., vol. 25, p. 590. (Described as below as a new variety.)

The shell is uniformly larger and the vertical median line of the false area more depressed, incurved, and distinct than those of *Acrotreta microscopica* (Shumard) and the variety *tetonensis* Walcott. Some of the specimens of the ventral valves beautifully illustrate the effects of compression. One shell (Pl. LXVII, figs. 4' and 4'') is like that of *Acrotreta attenuata* Meek and the other (Pl. LXVII, figs. 4a and 4a') resembles the low form of *A. ophirensis* Walcott with the apex overhanging the false area. The surface of the shells embedded in the fine-grained sandstone has a papillose surface resulting from the indenting of the shell by the grains of sand, whereas those from limestone are marked only by fine concentric striae.

FORMATION AND LOCALITY.—Middle Cambrian: (11k) Sandstones of the "Edgewise beds," beneath the Elvins formation, St. Francois County; and (11e) thin-bedded limestones south-southwest of Potosi, Washington county; both in Missouri.

ACROTRETA MICROSCOPICA TETONENSIS Walcott.

Plate LXVII, figures 3, 3a-d.

Acrotreta microscopica tetonensis WALCOTT, 1902, Proc. U. S. Nat. Mus., vol. 25, p. 590. (Characterized as below as a new variety.)

This neat little shell possesses the characters of *Acrotreta microscopica* (Shumard) and *A. idahoensis* Walcott, but differs from both by the projection of the apex of the ventral valve

over the false area. All that is known of it is represented by the illustrations (Pl. LXVII, figs. 3, 3a-d).

The varietal name is derived from the Teton Mountains, Wyoming.

FORMATION AND LOCALITY.—**Middle Cambrian:** (4e) Limestones about 950 feet (289.6 m.) above the unconformable base of the Cambrian in the divide at the head of Jackson Creek (locally known as Sheep Creek), a creek flowing into Jackson Lake about 0.5 mile (0.8 km.) south of its northwestern corner, Teton Mountains, Grand Teton quadrangle (U. S. Geol. Survey), Uinta County, Wyoming.

ACROTRETA ? MINIMA (Barrande).

Plate LXXVII, figures 7, 7a.

Obolus ? minimus BARRANDE, 1879, *Système silurien du centre de la Bohême*, vol. 5, pt. 1, Pl. XCV, figs. 11: 1-5. (Not described, but figured as a new species. Figs. 3A and 1A are reproduced in this monograph, Pl. LXXVII, figs. 7 and 7a, respectively.)

This minute shell may possibly belong with *Acrothele*, but with the data furnished by the illustrations of Barrande [1879b, Pl. XCV, figs. 11:1-5] a provisional reference is made to *Acrotreta*. It certainly is not an *Obolus*. The figures illustrate all the characters known.

FORMATION AND LOCALITY.—**Lower Ordovician:** (303d [Barrande, 1879b, Pl. XCV] Étage d1, Swarow, Bohemia, Austria-Hungary.

ACROTRETA MISERA (Billings).

Plate LXXII, figures 2, 2a-1.

Obolella ? miser BILLINGS, 1872, *Canadian Naturalist*, 2d ser., vol. 6, No. 4, pp. 470-471. (Described and discussed.)
Obolella ? miser BILLINGS, 1874, *Geol. Survey Canada, Paleozoic Fossils*, vol. 2, pt. 1, p. 69. (Copy of preceding reference.)

Linnarssonina misera (Billings), MATTHEW, 1886, *Trans. Roy. Soc. Canada for 1885*, 1st ser., vol. 3, sec. 4, No. 4, pp. 35-36, Pl. V, figs. 12, 12a-e. (Described and discussed.)

Linnarssonina misera (Billings), HALL and CLARKE, 1892, *Nat. Hist. New York, Paleontology*, vol. 8, pt. 1, pp. 108-109, Pl. III, figs. 35-37. (Mentioned. Figs. 35 and 36 are drawn from the specimens figured by Matthew, 1886, Pl. V, figs. 12c and 12, respectively.)

Acrotreta miser (Billings), WALCOTT, 1902, *Proc. U. S. Nat. Mus.*, vol. 25, pp. 590-591. (Described essentially as below.)

The abundant material representing this species that I collected in Newfoundland gives illustrations that present its characters with such fullness and detail that minute description is unnecessary. Plate LXXII, figures 2, 2a-e of the ventral valve, show variation in outline, also of the cast of the apical callosity, cardinal scars, and base of main vascular sinuses. Figures 2h-1 illustrate the interior of the dorsal valve.

The outer surface is marked by fine concentric striæ and growth lines, and the inner layers or lamellæ by very fine radiating striæ. The minute pedicle aperture is on the back side of the apex, opening almost posteriorly in some examples.

This is a small species, averaging from 1.5 to 2.5 mm. in length.

FORMATION AND LOCALITY.—**Middle Cambrian:** (1 and 2) Shales of zones A and B, respectively, of No. 7 of the Manuels Brook section [Walcott, 1891b, p. 261], Manuels Brook, Conception Bay; (314 [Billings, 1872b, p. 470]) *Paradoxides* zone on Chapple Arm, Trinity Bay; (314h) shale on Manuels Brook, Conception Bay; (6g) limestone near the base of the Middle Cambrian, northwest side of Chapple Arm Harbor, about 1 mile (1.6 km.) from its head, Trinity Bay; (6h) limestone in the southwest cove of Chapple Arm, Trinity Bay; and (6r) limestone on the west side of Manuels Brook, Conception Bay; all in Newfoundland.

(2s and 2t) Shales and interbedded limestones in the upper part of the *Paradoxides* zone, Hastings Cove [Matthew, 1898b, p. 38], on Kennebecasis Bay, 0.5 mile (0.8 km.) northeast of Torryburn, on the Intercolonial Railway, north-east of St. John; and (3011 [Matthew, 1886, p. 36]) shale of Division 1d of Matthew, on Porters Brook, St. Martins; both in St. John County, New Brunswick, Canada.

ACROTRETA NEBOENSIS Walcott.

Plate LXXVII, figures 9, 9a-b.

Acrotreta nevoensis WALCOTT, 1905, *Proc. U. S. Nat. Mus.*, vol. 28, pp. 300-301. (Described as below as a new species.)

Ventral valve moderately elevated, the apex projecting slightly over the nearly vertical false area. The latter is marked midway by a very narrow false pedicle furrow. The transverse

dorsal valve has a strong median depression which starts on the umbo and widens out rapidly toward the front.

The surface of the shell is marked by concentric ridges and lines of growth and very fine concentric striae.

Observations.—This is one of the *Acrotreta idahoensis* forms of the genus. It differs from other described forms in the strong median depression of the dorsal valve.

The specific name is derived from Mount Nebo Canyon, the type locality.

FORMATION AND LOCALITY.—**Middle Cambrian:** (14t) Limestone lying on slope between the Cambrian quartzite and the massive blue limestone 100 feet (30.5 m.) above, in Mount Nebo Canyon, 3 miles (4.8 km.) southeast of Mona, Juab County, Utah.

ACROTRETA NICHOLSONI Davidson.

Plate LXXIII, figures 1, 1a-k, 6, 6a-b.

Acrotreta? nicholsoni DAVIDSON, 1868, Geol. Mag., vol. 5, pp. 313-314, Pl. XVI, figs. 14-16. (Described and discussed as a new species; see below for copy of description. Figs. 14, 15, and 16 are reproduced in this monograph, Pl. LXXIII, figs. 1, 1c, and 1d, respectively.)

Acrotreta? nicholsoni DAVIDSON, 1871, British Fossil Brachiopoda, vol. 3, pt. 7, No. 4, pp. 343-344, Pl. XLIX, figs. 36-40. (Described and discussed. Figs. 36, 37, and 40 are copied from figs. 15, 14, and 16, respectively, of the preceding reference. Figs. 38 and 39 are reproduced in this monograph, Pl. LXXIII, figs. 1a and 1b, respectively.)

Acrotreta nicholsoni DAVIDSON, SWANSTON, 1877, Proc. Belfast Naturalists' Field Club, Appendix 4 for 1876-77, Pl. VII, figs. 21a-c. (Not described. Figs. 21b and 21c are copied from Davidson, 1868, Pl. XVI, figs. 14a and 14b.)

Acrotreta nicholsoni DAVIDSON, 1883, British Fossil Brachiopoda, vol. 5, pt. 2, p. 213, Pl. XVI, figs. 21-23. (New localities mentioned and new figures given. Figs. 21a, 21c, 21b, 22a, 22b, 21d, and 22c are reproduced in this monograph, Pl. LXXIII, figs. 1e-1k, respectively.)

Acrotreta nicholsoni DAVIDSON, SWANSTON, 1886, Systematic Lists, Flora, Fauna, Paleontology, and Archæology, North of Ireland, vol. 1, Pl. VII, figs. 21a-c. (Reprint of Swanston, 1877, Pl. VII, figs. 21a-c.)

Acrotreta nicholsoni DAVIDSON, HALL and CLARKE, 1892, Nat. Hist. New York, Paleontology, vol. 8, pt. 1, p. 103, fig. 59. (Mentioned in the text and fig. 59 copied from Davidson, 1868, Pl. XVI, fig. 16a.)

The original description by Davidson follows:

Shell small, about 2 lines in length by about the same in breadth, almost circular; rather wider and broadly rounded anteriorly; nearly straight posteriorly; dorsal valve very slightly convex; ventral valve conical; apex subcentral and truncated by a minute circular foramen, situated at a little more than one-third of the length of the valve. From the center of the posterior margin a narrow groove or channel extends to the base of the foramen, while on either side a small, flattened triangular space or false area (?) is limited by an indented line. Surface of both valves marked with numerous concentric lines of growth.

Subsequently Davidson obtained some less-compressed specimens and reillustrated [1883, Pl. XVI, figs. 21-23] the species. In order to bring before the student all available information I have reproduced most of Davidson's figures.

Observations.—*A. nicholsoni* is one of the largest species of the genus and one of the latest in point of time. Davidson [1883, Pl. XVI, figs. 21-23] illustrates specimens 5 to 6 mm. in length, and it ranges up into the Llandeilo.

The strongly marked false area and the high ventral valve serve to distinguish this species.

The specific name was given in honor of Nicholson.

FORMATION AND LOCALITY.—**Lower Ordovician:** (316 [Davidson, 1871, p. 343]) Upper Llandeilo (?) black shales, at Dobbs Linn, near Moffat, Dumfriesshire; and (316a [Davidson, 1883, p. 213]) Llandeilo at Craighead, Ardmillan Brae, and Balcletchie, all in the Girvan district of Ayrshire; both in Scotland.

(317 [Davidson, 1883, p. 213]) Coalpit Bay, County Down, Ireland.

Upper Cambrian: (304h) Shineton shales at Mary Dingle, South Shropshire; and (304a [Groom, 1902, p. 110]) "Bronsil" shales, Malvern Hills; both in England.

ACROTRETA NOX Walcott.

Plate LXXVII, figure 10.

Acrotreta nox WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 301. (Characterized as below as a new species.)

This minute shell, 1 mm. in length, is characterized by its low ventral valve, nipple-like apex, and apparently smooth surface.

FORMATION AND LOCALITY.—**Upper Cambrian:** (10v) Shales in "St. Croix sandstone," at Fox Glen, 8 miles (12.8 km.) east of Baraboo, Sauk County, Wisconsin.

ACROTRETA OELANDICA Westergård.

Acrotreta oelandica WESTERGÅRD, 1909. Medd. från Lunds Geol. Fältklubb, Ser. B, No. 4 (Aftryck ur K. Fysiografiska Sällskapet's Handl., N. F., Bd. 20), p. 76, Pl. V, figs. 24a-b. (Described in Swedish as a new species; see below for translation.)

The original description by Westergård follows:

Apex situated near the posterior border. Along the latter there is a faintly defined triangular area which occupies one-fourth of the periphery of the shell. The shell is about half as high as broad. Surface smooth, with fine distinct growth lines, which, although more faintly, are also to be seen on the area. The slope from the apex to the anterior border is slightly concave, though this is likely a secondary phenomenon due to pressure. The apex itself has not been preserved.

FORMATION AND LOCALITY.—Upper Cambrian: (310r) Zone v. of the *Ceratopyge* slate at Ottenby, Oeland Island; and (310s) uppermost part of the alum slate in beds equivalent to the *Ceratopyge* slate, northern part of Oeland Island; both [Westergård, 1909, p. 76] in Sweden.

ACROTRETA OPHIRENSIS Walcott.

Plate LXXIV, figures 1, 1a-p.

Acrotreta ophirensis WALCOTT, 1902, Proc. U. S. Nat. Mus., vol. 25, pp. 591-592. (Described as below as a new species.)

General outline transversely broad oval, sometimes nearly circular, with the posterior margin slightly indented midway on the ventral valve by incurving to the false pedicle furrow. The ventral valve is convex and moderately elevated, the highest point being in front of the pedicle aperture at about one-third the diameter of the shell. Pedicle aperture large for the size of the shell and opening either directly or obliquely backward; one specimen shows an obscure, short, narrow, triangular false area, with a vertical furrow crossing it (Pl. LXXIV, fig. 1a''); false area scarcely defined by the cardinal slopes, which incurve very gently; median furrow well defined, rather strong, and nearly flat on the bottom, the margins being sharply outlined in many specimens. Some of the shells curve over the false area so that the depressed apex extends slightly beyond the posterior margin, but generally it is directly on the line of, or a little in front of, the posterior margin.

Longitudinal diameter of average size ventral valve 3 mm., with a length of 2 to 2.5 mm.; elevation, 1.5 mm. A few shells have nearly the same length and width. The convexity of the dorsal valve averages 0.75 mm. The minute beak of the dorsal valve curves down to the posterior margin from the somewhat swollen posterior third of the valve.

Surface marked by fine concentric striæ and lines of growth, some of which form concentric ridges. The shell is built up of a thin outer layer and numerous thin inner layers or lamellæ that are oblique to the outer layer over the central and outer portions, the obliquity increasing toward the outer anterior and lateral margins.

The interior of the ventral valve shows a rather strong apical callosity that extended nearly to the posterior inner margin of the shell; distinct, but relatively small cardinal scars, and narrow main vascular sinuses that may be traced nearly to the anterolateral margins of the valve. The outlines of the visceral cavity are indicated on one well-preserved cast of the interior of the valve (Pl. LXXIV, fig. 1e). The interior of the dorsal valve shows great variation in the size and length of the median ridge and cardinal and central scars; these characters are fully shown in the numerous illustrations of the interior and casts of the interior of the dorsal valve.

Observations.—This species is most closely related to *Acrotreta curvata* Walcott. It differs in the ventral valve being larger, in the apex being less extended over the false area, and the form of the median furrow, which is like that of *A. attenuata* Meek. Although the shells occur in a compact unaltered limestone, there is more or less distortion in the outline of both valves; this, taken in connection with the variation in form and size of the vascular markings, muscle scars, and median ridge of the dorsal valve, might serve to discriminate several so-called varieties, but I have given names to only two of the more pronounced varieties.

Similar forms occur in a compact, dark, bluish-gray limestone more than 200 miles to the north in the Wasatch Mountains, east of Cache Valley, on the line of the Ute Peak section of the Fortieth Parallel Survey.

The specific name is derived from Ophir, the type locality.

FORMATION AND LOCALITY.—**Middle Cambrian:** (3e) *Limestone less than 400 feet (121.9 m.) above the quartzitic sandstones of the Cambrian, at Ophir, Oquirrh Range, Tooele County, Utah.*

(30n) About 3,750 feet (1,143 m.) above the Lower Cambrian and 650 feet (198 m.) below the Upper Cambrian, in the shaly limestones forming 1c of the Weeks limestone [Walcott, 1908f, p. 175], on the north side of Weeks Canyon, about 4 miles (6.4 km.) south of Marjum Pass; (30g) about 2,350 feet (716.3 m.) above the Lower Cambrian and 2,050 feet (624.8 m.) below the Upper Cambrian in the limestone forming 1c of the Marjum limestone; and (3x and 3y) about 2,200 feet (670.6 m.) above the Lower Cambrian and 2,200 feet (670.6 m.) below the Upper Cambrian in the shaly limestones forming 1d of the Marjum limestone [Walcott, 1908f, p. 180], in the ridge east of Wheeler Amphitheater; all in the House Range [Walcott, 1908f, Pl. XIII], Millard County, Utah.

(31z and 55t) About 350 feet (106.7 m.) above the Brigham quartzite in limestone of the Ute limestone [Walcott, 1908f, p. 7], on west side of road, 0.5 mile (0.8 km.) above the forks, Paradise Dry Canyon (locally known as East Fork), east of Paradise, Cache County, Utah.

ACROTRETA cf. OPHIRENSIS Walcott.

Numerous compressed specimens of shells about the size of *Acrotreta ophirensis* Walcott occur in strata of Middle Cambrian age at various localities in Utah. They resemble the latter species in size, occasional strong lines of growth, position of the apex of the ventral valve, and strong cardinal muscle scars in the dorsal valve; they differ in being much less convex, and in having only a trace of shell substance; the removal of the shell by solution and the compression in the shale accounts very largely for the differences. The stratigraphic position of the two forms is about the same and they both lived in the eastern portion of the Cordilleran Middle Cambrian Sea.

FORMATION AND LOCALITY.—**Middle Cambrian:** (32j) 625 feet (190.5 m.) above the top of the Cambrian quartzitic sandstone in pinkish-colored very fine grained arenaceous shale, 2 miles (3.2 km.) southeast of Muskrat Spring, on the northwest face of Grantsville Peak, Stansbury Range, Tooele County, Utah.

(31v) 650 feet (198.1 m.) above the Lower Cambrian and 3,750 feet (1,143 m.) below the Upper Cambrian, in shales at the top of the limestone forming 1a of the Howell formation [Walcott, 1908f, p. 182], northeast side of Dome Canyon, about 4 miles (6.4 m.) west-southwest of Antelope Springs; (31y and 30g) about 2,350 feet (716.3 m.) above the Lower Cambrian and 2,050 feet (624.8 m.) below the Upper Cambrian in 1c of the Marjum limestone [Walcott, 1908f, p. 180], ridge east of Wheeler Amphitheater; and (31s) 490 feet (149.4 m.) above the Lower Cambrian and 3,925 feet (1,196.3 m.) below the Upper Cambrian, in the pinkish argillaceous shale forming 1d of the Howell formation [Walcott, 1908f, p. 182], south side of Dome Canyon about 1 mile (1.6 km.) below the divide, and 3 miles (4.8 km.) west-southwest of Antelope Springs; all in the House Range [Walcott, 1908f, Pls. XIII and XVI], Millard County, Utah.

(31c) About 900 feet (274.3 m.) above the Brigham quartzite and 3,300 feet (1,005.8 m.) below the Upper Cambrian, in the limestone forming 1b of the Ute limestone [Walcott, 1908f, p. 196], in Blacksmith Fork Canyon, about 10 miles (16.1 km.) east of Hyrum, Cache County; (32c) about 60 feet (18.3 m.) above the Brigham quartzite [Walcott, 1908a, p. 8], in green shale, 1 mile (1.6 km.) northwest of Geneva (Copenhagen), east of Brigham, Boxelder County; and (30u) about 250 feet (76.2 m.) above the Cambrian quartzitic sandstones in sandy shales, 4 miles (6.4 km.) northwest of Promontory Point (on the "Lucin cut-off" of the Union Pacific Railway), about halfway up west end of ridge, north of Great Salt Lake, Boxelder County; all in Utah.

ACROTRETA OPHIRENSIS DESCENDENS Walcott.

Plate LXXVIII, figures 1, 1a-c.

Acrotreta ophirensis descendens WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 3, p. 95, Pl. IX, figs. 1 and 1a. (Discussed as below as a new variety. Figs. 1 and 1a are copied in this monograph, Pl. LXXVIII, figs. 1 and 1c, respectively.)

In the Cambrian section of the House Range, Utah, the typical forms of *Acrotreta ophirensis* occur in the Marjum limestone; 1,570 feet higher in the section, in the Weeks limestone, there are great numbers of a shell identical in many respects. This latter shell differs from the typical form in being less convex in both the ventral and dorsal valves, and in having a more pointed, less curved apex on the ventral valve.

This form owes its varietal name to the fact that it occurs higher in the section than the species, and is probably descendant from it.

FORMATION AND LOCALITY.—**Middle Cambrian:** (30n) About 3,750 feet (1,143 m.) above the Lower Cambrian and 650 feet (198 m.) below the Upper Cambrian in shaly limestones forming 1c of the Weeks limestone [Walcott, 1908f, p. 175], on the north side of Weeks Canyon, about 4 miles (6.4 km.) south of Marjum Pass, House Range [Walcott, 1908f, Pl. XIII], Millard County, Utah.

ACROTRETA OPHIRENSIS RUGOSA Walcott.

Plate LXXIV, figures 2, 2a-e.

Acrotreta ophirensis rugosus WALCOTT, 1902, Proc. U. S. Nat. Mus., vol. 25, p. 592. (Characterized as below as a new variety.)

This form is associated with *Acrotreta ophirensis* Walcott in considerable numbers. It is characterized by strong, rugose growth lines and thicker shell.

FORMATION AND LOCALITY.—**Middle Cambrian:** (3e) Thin-bedded limestone, less than 400 feet (121.9 m.) above the quartzitic sandstones of the Cambrian, at Ophir, Oquirrh Range, Tooele County, Utah.

ACROTRETA OVALIS Walcott.

Plate LXVI, figures 2, 2a-b.

Acrotreta ovalis WALCOTT, 1902, Proc. U. S. Nat. Mus., vol. 25, p. 592. (Characterized as below as a new species.)

In material received from the Geological Survey of Canada in answer to a request for the specimens representing *Acrotreta gemma* Billings, there was one ventral valve embedded in a smooth, dove-colored limestone from Point Levis. This specimen differs materially from *A. gemma* in the oval outline of the rim of the shell, less elevated apex, and less well-defined false area. It is more of the type of *A. schmalensei* Walcott, and of *A. microscopica* (Shumard) of the interior continental species than any of the Atlantic Province forms.

FORMATION AND LOCALITY.—**Lower Ordovician:** (319 [Geol. Survey, Canada]) Limestone No. 1 of Billings's Point Levis Section, Point Levis, Province of Quebec, Canada.

ACROTRETA PACIFICA Walcott.

Plate LXIX, figures 6, 6a-e.

Acrotreta pacifica WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 301. (Described below as a new species.)

Ventral valve a high cone, with the apex a little in advance of the posterior margin; base circular, with the exception of a slight flattening on the posterior side; apex acute and pointing upward; false area only a slight flattening of the shell from the apex to the margin. The largest ventral valve has a diameter and height of about 1.5 mm. Surface marked by fine concentric striæ that continue without noticeable deflection across the false area.

Observations.—Only two specimens of the ventral valve of this species occur in the collection. One of these has a slightly transverse, broadly oval base, and a more definite false area. The species is closely related to *Acrotreta idahoensis alta* Walcott except that the ventral valve is not quite as elevated.

FORMATION AND LOCALITY.—**Middle Cambrian:** (C1 and C2) Lower shale member of the Kiulung group [Blackwelder, 1907a, pp. 37 and 40 (part of the 3d list of fossils) and fig. 10 (beds 4 and 5), p. 38], 2 miles (3.2 km.) south of Yenchuang; (C12) gray limestone near the top of the middle limestone member of the Kiulung group [Blackwelder, 1907a, pp. 37 and 41 (part of the first list of fossils) and fig. 10 (bed 7), p. 38], 3.25 miles (5.2 km.) southwest of Yenchuang; (C5) lower limestone member of the Kiulung group [Blackwelder, 1907a, pp. 37 and 39 (first list of fossils), and fig. 8a (bed 30), p. 29], 3.2 miles (5.1 km.) southwest of Yenchuang; and (C4) limestone nodules at the base of the lower shale member of the Kiulung group [Blackwelder, 1907a, pp. 37 and 40 (2d list of fossils), and fig. 10 (bed 4), p. 38], 3 miles (4.8 km.) southwest of Yenchuang; all in the Sintai district, Shantung, China.

ACROTRETA PARVULA (Wallerius).

Plate LXXVII, figures 4, 4a.

Obolella parvula WALLERIUS, 1895, Undersökningar öfver Zonen med *Agnostus lævigatus* i Vestergötland, pp. 65-66, figs. 9a-d. (Described in Latin, and discussed in Swedish.)

Acrotreta parvula (Wallerius), WALCOTT, 1902, Proc. U. S. Nat. Mus., vol. 25, p. 592. (Described as on p. 700.)

Shell minute, subcircular. Ventral valve relatively depressed, the highest point being at the umbo, from which there is a slight downward curvature to the apex. False area low and about vertical, the apex being on a line with the posterior margin. Dorsal valve slightly convex; beak marginal. Surface marked by fine concentric striae.

Observations.—This minute species occurs with *Agnostus lævigatus* in the upper portion of the Middle Cambrian. It is of the *Acrotreta sagittalis* (Salter) type, but does not appear to be identical with the young of that species.

FORMATION AND LOCALITY.—**Middle-Upper Cambrian:** (310i) Passage beds between the Middle Cambrian *Paradoxides forchhammeri* zone and the Upper Cambrian *Olenus truncatus* zone, limestone at Borgholm, Oeland Island, Sweden.

Middle Cambrian: (320) Gudhem, 12.5 miles (20.1 km.) south-southeast of Skara; and (320a) *Djupadal*, 19 miles (30.6 km.) south-southeast of Skara; both [Wallerius, 1895, p. 66] in the Province of Skaraborg, Sweden.

ACROTRETA PRIMÆVA Walcott.

Plate LXIX, figures 1, 1a-f.

Acrotreta gemma WALCOTT (in part) [not BILLINGS], 1886, Bull. U. S. Geol. Survey No. 30, pp. 98-99, Pl. VIII, figs. 1, 1a-b. (Specimens now referred to *Acrotreta pyxidicula* and *A. attenuata* were included with the specimens representing *A. primæva* when this description of *A. gemma* was written, but they were not figured. The two specimens represented by figs. 1b and 1, 1a are redrawn in this monograph, Pl. LXIX, figs. 1c and 1, respectively.)

Acrotreta gemma WALCOTT (in part) [not BILLINGS], 1891, Tenth Ann. Rept. U. S. Geol. Survey, p. 608, Pl. LXVII, figs. 5c, 5d, and 5e (not figs. 5, 5a-b, see below). (Figs. 5c, 5d, and 5e are copied from figs. 1a, 1, and 1b, respectively, of preceding reference. Specimens now referred to *Acrotreta attenuata*, *A. idahoensis alta*, and *A. curvata* were included with the specimens representing *A. primæva* in this reference to *A. gemma*, but only the last two were figured: *A. idahoensis alta*, Pl. LXVII, figs. 5 and 5a, and *A. curvata*, Pl. LXVII, fig. 5b.)

Acrotreta gemma WALCOTT (in part) [not BILLINGS], 1899, Mon. U. S. Geol. Survey, vol. 32, pt. 2, p. 449, Pl. LXII, figs. 2, 2b, and 2d (not figs. 2a, 2c, and 2e, see below). (Figs. 2, 2b, and 2d are copied from Walcott, 1886b, Pl. VIII, figs. 1, 1a, and 1b, respectively. Specimens now referred to *Acrotreta pyxidicula*, *A. attenuata*, *A. idahoensis alta*, and *A. curvata* were included with the specimens representing *A. primæva* when this description of *A. gemma* was written, but only the last two were figured; *A. idahoensis alta*, Pl. LXII, figs. 2a and 2c, and *A. curvata*, Pl. LXII, fig. 2e.)

Acrotreta primæva WALCOTT, 1902, Proc. U. S. Nat. Mus., vol. 25, p. 593. (Described essentially as below as a new species.)

Acrotreta gemma Walcott, GRABAU and SHIMER [not BILLINGS], 1907, North American Index Fossils, vol. 1, p. 199, figs. 234a-c. (Described, and figures copied from Walcott [1886b, Pl. VIII] figs. 1a, 1, and 1b, respectively.)

Outline of valves transversely oval to subcircular. Ventral valve subconical, with the apex at the summit of the false area near or just above the posterior margin. The elevation varies from one-half to two-thirds the diameter of the shell. The false area is quite clearly defined in most specimens; it varies in width at the posterior margin from one-third to nearly one-half of the diameter of the shell; the path of advance of the pseudodeltidium is marked usually by a narrow incised line similar to that of *Acrotreta attenuata* Meek. Foraminal aperture minute and situated at the apex of the cone. Dorsal valve slightly convex, with a minute beak slightly incurved over the posterior margin. A broad, slightly defined median sinus flattens the front and central portion of the valve, but it is not perceptible toward the umbo and beak. Surface of the shell marked by fine concentric striae and occasional ridges of growth; on some shells there is a very fine, almost microscopic, irregular, concentric striation that gives a fretted surface somewhat similar to that of *Obolus (Westonia) ella* (Hall and Whitfield). The inner lamellæ of the shell and the interior surface have traces of fine radiating striae that, with the irregular concentric striae, give a broken, subimbricated, fretted effect to the surface. The shell is formed of a thin outer layer and several thin inner layers or lamellæ, the outer ones of which are slightly oblique to the outer surface layer. The largest shells have a transverse diameter of 5.5 mm., longitudinal diameter 5 mm., height of ventral valve 3 mm.; dorsal valve 1 mm. The interior of a slightly crushed ventral valve, figure 1e, shows the cast of an apical callosity, strong vascular canals, and faint outlines of the visceral cavity. The cast of an interior of a dorsal valve has a long, well-defined median ridge, cardinal scars, and faintly defined central scars, as illustrated by figures 1d and 1f. Interiors of the ventral valve from near

Cherry Creek show two relatively small cardinal scars near the posterior margin, and a small subtriangular apical callosity.

Observations.—This, the oldest species of the genus known to me, has all the essential characters of the type species as far as the available information permits of comparison. It is one of the largest shells of the genus, and is a striking feature of the fauna of the higher portion of the *Olenellus* zone of central Nevada. The most nearly related species appears to be *A. attenuata* Meek (Pl. LXIV, fig. 1).

FORMATION AND LOCALITY.—**Middle Cambrian:** (7j) Limestones at the north end of the Quinn Canyon Range, 1 mile (1.6 km.) northwest of the Italian Ranch foothills, Nye County, Nevada.

Lower Cambrian: (41) Limestone in the Pioche formation [Walcott, 1908a, p. 11] on a ridge 2.5 miles (4 km.) northwest of the town of Cherry Creek, White Pine County; and (31a) limestone and interbedded siliceous shales of the Pioche formation [Walcott, 1908a, p. 11], just above the quartzite on the east side of the anticline, near Pioche, Lincoln County; both in Nevada.

ACROTRETA PYXIDICULA White.

Plate LXIX, figures 2, 2a-f, 3, 3a-f.

Acrotreta pyxidicula WHITE, 1874, U. S. Geog. Surveys W. 100th Mer., Prelim. Rept. Invertebrate Fossils, p. 9. (Described as a new species.)

Acrotreta pyxidicula WHITE, 1877, U. S. Geog. Surveys W. 100th Mer., vol. 4, pt. 1, pp. 53-54, Pl. III, figs. 3a-d. (Described essentially as in preceding reference. The specimens represented by figs. 3a-b and 3c-d are redrawn in this monograph, Pl. LXIX, figs. 2 and 2f, respectively.)

Acrotreta gemma WALCOTT (in part) [not BILLINGS], 1884, Mon. U. S. Geol. Survey, vol. 8, pp. 17-18. (Specimens representing *Acrotreta attenuata*, *A. curvata*, and *A. idahoensis alta* were included with the specimens representing *A. pyxidicula* when this description of *A. gemma* was written, but only the last two are known to have been figured: *A. curvata*, Pl. I, figs. 1d and 1e, and *A. idahoensis alta*, Pl. I, figs. 1a and 1b. The specimens represented on Pl. IX, figs. 9 and 9a, can not be positively located at this time, but it is probable that they should be referred to *A. idahoensis alta*.)

Acrotreta gemma WALCOTT (in part) [not BILLINGS], 1886, Bull. U. S. Geol. Survey No. 30, pp. 98-99. (Specimens now referred to *Acrotreta attenuata* and *A. primæva* were included with the specimens representing *A. pyxidicula* when this description of *A. gemma* was written, *A. primæva* being figured, Pl. VIII, figs. 1, 1a-b.)

Acrotreta gemma WALCOTT (in part) [not BILLINGS], 1891, Tenth Ann. Rept. U. S. Geol. Survey, p. 608. (Specimens now referred to *Acrotreta attenuata*, *A. curvata*, *A. idahoensis alta*, and *A. primæva* were included with the specimens representing *A. pyxidicula* in this reference to *A. gemma*, the last three being figured: *A. curvata*, Pl. LXVII, fig. 5b; *A. idahoensis alta*, Pl. LXVII, figs. 5 and 5a; and *A. primæva*, Pl. LXVII, figs. 5c, 5d, and 5e.)

Acrotreta gemma WALCOTT (in part) [not BILLINGS], 1899, Mon. U. S. Geol. Survey, vol. 32, pt. 2, p. 449. (Specimens now referred to *Acrotreta attenuata*, *A. curvata*, *A. idahoensis alta*, and *A. primæva* were included with the specimens representing *A. pyxidicula* when this description of *A. gemma* was written, the last three being figured: *A. curvata*, Pl. LXII, fig. 2e; *A. idahoensis alta*, Pl. LXII, figs. 2a and 2c; and *A. primæva*, Pl. LXII, figs. 2, 2b, and 2d.)

This is a small and very pretty species in which the interiors of the two valves are fairly well shown by casts. A marked feature of the ventral valve is the very strong vascular sinus (fig. 3f), and of the dorsal valve the thickening of the shell in the posterior portion (fig. 3e). The surface of the shell is marked by fine concentric striæ and occasional lines of growth. It is one of the small species of the genus, the average size being from 1.5 to 2 mm. Of the known species it may be compared with *A. idahoensis* Walcott (Pl. LXV) from which it differs in the slighter elevation of its ventral valve and the incised median line on the false area.

FORMATION AND LOCALITY.—**Upper Cambrian:** (313f) Limestone at Schellbourne, Schell Creek Range, White Pine County, Nevada.

(329d) Limestone near Fish Springs, Fish Spring Range, Juab County, Utah.

Middle Cambrian: (7j) Limestone at the north end of the Quinn Canyon Range, 1 mile (1.6 km.) northwest of the Italian Ranch foothills, Nye County; and (60) limestone in upper beds of Secret Canyon shale, across the canyon from the dump of the old Richmond mine shaft, Eureka district [Hague, 1892, Atlas], Eureka County; all in Nevada.

(30z) About 2,450 feet (746.8 m.) above the Lower Cambrian and 1,950 feet (594.4 m.) below the Upper Cambrian, in the upper part of the limestone forming 1c of the Marjum limestone [Walcott, 1908f, p. 180], in the long cliff about 2 miles (3.2 km.) southeast of Marjum Pass, House Range [Walcott, 1908f, pls. XIII and XV], Millard County, Utah.

(5b and 54s) Dark blue-gray Langston limestone [Walcott, 1908f, p. 198], just above the Cambrian quartzitic sandstones, north side of Twomile Canyon, near its mouth, 2 miles (3.2 km.) southeast of Malade, Oneida County; (59f) limestones immediately underlying the Spence shale member of the Ute limestone [Walcott, 1908a, p. 8], in a saddle

north of the creek which flows into Mill Canyon from the west, about 5 miles (8 km.) west-southwest of Liberty and 15 miles (24.2 km.) west of Montpelier, Bear Lake County; and (322) limestone (stratigraphic position unknown) about 6 miles (9.6 km.) west-southwest of Liberty and 15 miles (24.2 km.) west of Montpelier, Bear Lake County; all in Idaho.

(4h) About 375 feet (114.3 m.) above the base of the Cambrian in the limestone interbedded in the Flathead shales of Peale [1893, p. 21], 1 mile (1.6 km.) north of the junction of East Gallatin and West Gallatin (Gallatin) rivers, 4 miles (6.4 km.) east-northeast of Logan, Threeforks quadrangle (U. S. Geol. Survey), Gallatin County, Montana.

ACROTRETA RUDIS Walcott.

Plate LXXV, figure 3f; Plate LXXXV, figure 1.

Acrotreta kutorgai WALCOTT (in part), 1902, Proc. U. S. Nat. Mus., vol. 25, pp. 589-590. (Described as a new species, but the description included specimens belonging to both *Acrotreta kutorgai* and *A. rudis*.)

Acrotreta rudis WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 3, pp. 95-96, Pl. IX, fig. 5. (Described and discussed as below as a new species. Fig. 5 is copied in this monograph, Pl. LXXV, fig. 3f.)

The specimens illustrating this species are all more or less crushed and flattened on the surface of the fine argillaceous shale in which they are embedded in large numbers, and they are often in the condition of casts of the interior of the valves. This is well shown by the enlargement of a fragment of the shale on which three ventral and three dorsal valves occur (Pl. LXXXV, fig. 1).

The ventral valve, as far as can now be determined, was elevated, conical, and with the apex overhanging the false area, so that when the shells were crushed down the posterior side disappeared beneath. A few fragmentary specimens show the false area to have been distinctly defined, of medium height, and marked by a narrow, shallow median furrow extending from the apex to the margin of the valve. Dorsal valve subcircular, slightly transverse, gently convex, and with a minute beak at the posterior margin. The pedicle opening appears to have been of medium size and situated at the apex of the valve.

Surface marked by lines of growth and very fine concentric striæ that continue across the false area and furrow.

The cast of the interior of the ventral valve shows a small but well-defined visceral area in advance of the apex and a short strong main vascular sinus on each side of the area; one cast shows traces of the sinuses nearly to the front margin. The interior of the dorsal valve is marked by a strong median septum or ridge that extends from the front of a small cardinal area forward nearly to the anterior margin in some examples. A large, oval cardinal muscle scar occurs on each side of the median ridge near the posterior border of the valve; the central muscle scars are small, elongate oval and situated on the sides of the median ridge at about the posterior third of the longitudinal axis of the shell; the two anterolateral muscle scars are on the sides of the median ridge a little in advance of the central scars.

This is one of the large species of the genus. A dorsal valve 4 mm. in length has a width of 4.5 mm. The ventral valves average from 4 to 4.5 mm. from the apex to the front margin.

In size and outline this species may be compared with *Acrotreta depressa* (Pl. LXVI, figs. 8, 8a-c) and *A. definita* (Pl. LXIV, figs. 2, 2a-g). It differs from both in its ventral valve being more elongate. All the specimens of *A. rudis* are so flattened in the shale that comparison with uncompressed specimens is very difficult.

FORMATION AND LOCALITY.—Middle Cambrian: (101a) Rogersville shale, just above the road in the hill west of the schoolhouse, 3.5 miles (5.6 km.) southwest of Rogersville on the road to Melinda Ferry [Keith, 1896a, areal geology sheet]; (102c) first shale south of the Estillville pike, 3.5 miles (5.6 km.) east of Rogersville, Greeneville quadrangle (U. S. Geol. Survey); and (121) Rogersville shale, road just east of Harlan Knob, 4 miles (6.4 km.) northeast of Rogersville [Keith, 1905, areal geology sheet]; all in Hawkins County, Tennessee.

ACROTRETA SABRINÆ (Callaway).

Plate LXXIII, figures 5, 5a-d.

Metoptoma sabrinæ CALLAWAY, 1874, Quart. Jour. Geol. Soc. London, vol. 30, pt. 1, p. 196. (Name proposed, not described.)

Obolella sabrinæ CALLAWAY, 1877, idem, vol. 33, pt. 1, p. 669, Pl. XXIV, fig. 12. (Described as a new species. The specimen represented by fig. 12 is redrawn in this monograph, Pl. LXXIII, fig. 5b.)

- Obolella sabrinæ* (Callaway), DAVIDSON, 1883, British Fossil Brachiopoda, vol. 5, pt. 2, p. 211, Pl. XVI, figs. 27, 27a, 27d, 28, and 28a. (Described and discussed.)
- Obolella? scabrinæ* (Callaway), WALCOTT, 1884, Mon. U. S. Geol. Survey, vol. 8, Pl. I, fig. 1c. (Not described, and figure copied from Davidson, 1883, Pl. XVI, fig. 27d.)
- Obolella sabrinæ* (Callaway), HALL and CLARKE, 1892, Nat. Hist. New York, Paleontology, vol. 8, pt. 1, p. 103, fig. 58. (Mentioned in the text and figure copied from Davidson, 1883, Pl. XVI, fig. 27d.)
- Acrotreta* sp. cf. *nicholsoni* Davidson, MATLEY, 1902, Quart. Jour. Geol. Soc. London, vol. 58, pt. 1, p. 142, fig. 10. (Discussed in text as *Acrotreta* sp., and figured as *A.* sp. cf. *nicholsoni*.)
- Acrotreta* (?) *sabrinæ* (Callaway), MATLEY, 1902, idem, p. 143. (Discussed.)
- Acrotreta* (?) *sabrinæ malvernensis* MATLEY, 1902, idem, pp. 143-144, figs. 11-14. (Described and discussed as a new variety.)
- Acrotreta* sp. cf. *A. socialis* von Seebach, MATLEY, 1902, idem, pp. 144-145, figs. 15 and 16. (Characterized and discussed.)

As in the case of most species of *Acrotreta* preserved in shales, the ventral valves of this form are so compressed as to prevent our getting the true elevation. With several fairly well-preserved specimens to judge from I think the height was about two-thirds of the greatest diameter of the shell. A partial cast of the interior shows a small apical callosity and the base of the cast of a small pedicle tube. The interior of the dorsal valve is almost bisected by a strong median ridge; the cardinal scars are also prominent.

A fragment of the outer shell shows fine, concentric striæ and lines of growth that are fretted by very fine undulating striæ.

Through the courtesy of Dr. Charles Lapworth I have had the opportunity of studying and illustrating the type specimen of Callaway's "*Obolella sabrinæ*" (Pl. LXXIII, fig. 5b). It is a cast of the dorsal valve preserving little more than the impression of the strong median ridge and a trace of the area. Dr. Lapworth also sent me several other specimens of this species; these are illustrated on Plate LXXIII, figures 5, 5a, 5c, and 5d. Davidson [1883, Pl. XVI, fig. 27d] illustrates an interior of a dorsal valve in which the median ridge and the cardinal and central scars are clearly defined. He also gives [1883, Pl. XVI, figs. 27, 27a] the exterior of a compressed ventral valve and a side view of the two valves united.

Of described species, *Acrotreta bisecta* Matthew approaches this most closely. It is quite probable that with a good series of specimens of each species for comparison the two forms would be referred to the one species of Callaway.

Matley [1902, p. 143, figs. 11-14] illustrates and describes some crushed specimens from the lowest black shales of the Malvern Hills, which he tentatively gives the value of a variety of this species under the name *malvernensis*. With examples from the typical locality before me for comparison with the proposed variety, I am inclined to consider the latter of such doubtful value as to leave it out of this work.

He also [Matley, 1902, p. 144] mentions an *Acrotreta* as sp. cf. *A. socialis* von Seebach from a higher stratigraphic horizon. *Acrotreta socialis* as now restricted is confined to the Middle Cambrian. I do not think that the material as illustrated and described by Matley clearly indicates a form distinct from *Acrotreta sabrinæ*, if allowance is made for the crushed condition of most specimens of the latter species. The shell mentioned as *Acrotreta* sp. cf. *nicholsoni* [Matley, 1902, p. 142] may also be a large specimen of this species.

The shells figured by Matley [1902, p. 141, figs. 7 and 8] as *Lingulella* (?) sp. and [1902, p. 142, fig. 10] as *Lingula* (?) sp. I think are either *Acrotreta* or *Acrothyra*, probably the latter.

FORMATION AND LOCALITY.^a—Upper Cambrian: (304h and 304i [Callaway, 1877, p. 669]) *Shinerton shale*, at *Shinerton, Mary Dingle, Dryton, Cressage*, 1 mile (1.6 km.) west of *Cressage*, west of *Harley*, and under *Cound-Moor quarry*, all in *South Shropshire, England*.

(304p) *Shinerton shales* at the following localities of the Geological Survey of Great Britain: 2495, 2536, 2543, 2545, 2558, and 2580, all of which are on *Shinerton Brook*, *South Shropshire, England*.

(304j) *Lower Stockingford shales*, *Puxley Park lane*, halfway up the path to the quarry, *Atherstone, Warwickshire*; (304a [Groom, 1902, p. 110]) "*Bronsil*" shales, *Malvern Hills*; and (304b [Groom, 1902, p. 109]) lower part of the "*White Leaved Oak*" shales (the zone of *Polyphyma*), *Malvern Hills*; all in *England*.

^a Localities 304h and 304j are the only localities represented in the United States National Museum collections. 304h is the type locality.

ACROTRETA SAGITTALIS (Salter).

Plate LXXI, figures 2, 2a-h, 3, 3a-j.

- Obolella sagittalis* SALTER, 1866, Rept. British Assoc. Adv. Sci. for 1865, p. 285. (Name proposed.)
- Discina labiosa* SALTER, 1866, idem, p. 285. (Name proposed.)
- Obolella sagittalis* Salter, DAVIDSON, 1868, Geol. Mag., vol. 5, pp. 309-310, Pl. XV, figs. 17-24. (Described and discussed.)
- Obolella sagittalis* Salter, DAVIDSON, 1871, British Fossil Brachiopoda, vol. 3, pt. 7, No. 4, pp. 339-340, Pl. L, figs. 1-14. (Copy of preceding reference. Figs. 1a, 3a, 4 and 4a, 5 and 5a, 9, 10 and 10a, and 12 and 12a appeared, Davidson, 1868, Pl. XV, as figs. 17a, 21a, 23 and 23a, 19 and 19a, 22a, 20 and 20a, and 24 and 24a, respectively.)
- Obolella sagittalis* Salter, LINNARSSON, 1876, Bihang till K. svensk. Vet.-Akad. Handl., Bd. 3, No. 12, pp. 19-20, Pl. III, figs. 36-41. (Described and discussed in English.)
- Obolella sagittalis* Salter, LINNARSSON, 1879, Sveriges Geol. Undersökning, Afhandl. och Uppsatser, Ser. C, No. 35, pp. 27-28, Pl. III, figs. 45-49. (Described in Swedish.)
- Obolella sagittalis* Salter, BRÖGGER, 1882, Die silurischen Etagen 2 und 3, p. 45, Pl. X, figs. 6-8. (Described and discussed in German.)
- Obolella sagittalis* Salter, DAVIDSON, 1883, British Fossil Brachiopoda, vol. 5, pt. 2, p. 211, Pl. XVI, figs. 25-26. (Gives new localities and new figures.)
- Linnarssonina sagittalis* (Salter), WALCOTT, 1885, Am. Jour. Sci., 3d ser., vol. 29, p. 115, figs. 5 and 8. (Merely refers the species to *Linnarssonina*. Figs. 5 and 8 are copied from Davidson, 1868, Pl. XV, figs. 22a and 23a, respectively.)
- Obolella ida*? DAWSON, 1888, Canadian Rec. Sci., vol. 3, p. 55. (Possible occurrence discussed.)
- Obolella ida*? DAWSON, 1888, Peter Redpath Museum, Montreal, Canada; Notes on Specimens, April, 1888, p. 55.
- Obolella* (*Linnarssonina*) *pretiosa* DAWSON, 1890, Trans. Roy. Soc. Canada for 1889, 1st ser., vol. 7, sec. 4, No. 3, pp. 53-54, figs. 26a-c. (Discussed.)
- Linnarssonina* cf. *pretiosa* Dawson, HALL, 1890, idem, p. 55. (Description of the specimens discussed in preceding reference.)
- Linnarssonina sagittalis* (Salter), WALCOTT, 1891, Tenth Ann. Rept. U. S. Geol. Survey, Pl. LXVIII, figs. 2a-d. (Not described.)
- Linnarssonina pretiosa* (Dawson), HALL and CLARKE, 1892, Nat. Hist., New York, Paleontology, vol. 8, pt. 1, p. 70, Pl. III, figs. 43-44. (Discussed. Figs. 43-44 are copied from Dawson, 1890, figs. 26a-c, p. 53.)
- Linnarssonina sagittalis* (Salter), HALL and CLARKE, 1892, idem, p. 108, figs. 60-61. (Discussed. The figures are copied from Davidson, 1868, Pl. XV, figs. 22a and 23a, respectively.)
- Linnarssonina pretiosa* (Dawson), SCHUCHERT (in part), 1897, Bull. U. S. Geol. Survey No. 87, p. 262. (Mere reference, but includes specimens now referred to both *Aerothele pretiosa* and *Acrotreta sagittalis*.)
- Linnarssonina sagittalis* (Salter), FRECH, 1897, additional plates inserted in 1897 in *Lethæa geognostica*, pt. 1, *Lethæa palæozoica*, Atlas, 1876, Pl. IA, fig. 3a. (No text reference. Fig. 3a is copied from Walcott, 1891a, Pl. LXVIII, fig. 2.)
- Obolella* cf. *sagittalis* Salter, WIMAN, 1902, Bull. Geol. Inst. Univ. Upsala, vol. 6, pt. 1, No. 11, p. 66. (New localities mentioned.)
- Obolella* (*Acrotreta*?) *sagittalis* (Salter), MOBERG and SEGERBERG, 1906, Medd. från Lunds Geol. Fältklubb, Ser. B, No. 2 (Afttryck ur K. Fysiografiska Sällskapets Handl., N. F., Bd. 17), p. 64, Pl. I, figs. 25 and 26. (Characterized in Swedish.)
- ?*Linnarssonina pretiosa* GRABAU and SHIMER, 1907, North American Index Fossils, vol. 1, p. 200. (Described, but not figured, and it is impossible to tell whether the authors are discussing the *L. pretiosa* that is now referred to *Acrotreta sagittalis*, or the true *Aerothele pretiosa*.)

Although I have examined a large collection of this species, both from Wales and Sweden, good exteriors of the valves have not been observed. The apex of the ventral valve almost invariably remains in the matrix, or the shell has been removed by solution. The convexity of the two valves is approximately the same (figs. 3c and 3d, Pl. LXXI) except that the ventral valve is more elevated near the apex. The apex is situated a little in front of the posterior margin at the edge of the slightly defined false area which slopes forward at an angle of 70° to 80°. The surface of the shell is marked by rather strong concentric striæ and often strong ridges of growth and very fine radiating striæ on the interior layers. The shell is built up of thin layers or lamellæ of a calcareoconeous nature. The average diameter of specimens from St. Davids, Wales, is 2.5 mm. The representatives of the species from Andrarum, Sweden, are usually smaller than the St. Davids shells but otherwise appear to be identical.

The interior of the ventral valve is shown by numerous casts. The apical callosity and the cardinal scars are usually large. The visceral cavity is sometimes outlined in front of the callosity and between the clearly marked main vascular sinuses. Casts of the interior of the

dorsal valve show a remarkable range of variation in the length and size of the median ridge (Pl. LXXI, figs. 3e, 3g-j). Within the extremes of variation specific characters could be established.

This species has had a varied experience at the hands of paleontologists. Davidson [1871, Pl. L, figs. 1-14] elaborately illustrated the casts of the interiors of the valves, and I [1885, p. 116] copied some of his figures when preparing the description of the genus *Linnarssonina*. When in Wales in 1888, I collected a quantity of material at St. Davids, and recently Schmalensee collected a good series at Andrarum for the United States National Museum. From these collections figures have been drawn that illustrate the appearance of the shells as they occur both in shalé and limestone.

The varieties *taconica* and *transversa* are strongly marked, but I think are not entitled to full specific valuation. A direct comparison of specimens from the black shales of Little Metis with those from the black shales of the type locality of *A. sagittalis* at St. Davids fails to disclose any specific differences between them, so far as the material at hand permits of comparison. The Little Metis shell was published as *Linnarssonina* cf. *pretiosa* by Hall [1890, p. 55], and this identification was accepted by Sir William Dawson [1890, p. 53]. "*Obolella pretiosa*" Billings [1862d, p. 68] is a true *Acrothele*, and no species of *Acrotreta* is known to occur at the type locality on the Chaudiere River. The stratigraphic horizon of the Little Metis beds has not been definitely determined. Dawson [1890, p. 32] says: "At Metis the evidence of the pebbles in the conglomerates indicates that they are newer than the Lower Cambrian, and the few fossils found in the sandstones and shales would tend to place them at or on the horizon of the Chazy." I personally examined the section at Little Metis in 1899, and am not at all certain of the horizon of the shales carrying *Acrotreta sagittalis* and the beautiful fossil sponges described by Dawson [1890, pp. 37-55]. It is a region of strong folding and thrust faults. The *Acrothele* is a Middle Cambrian type, and nothing similar to it is known from the Upper Cambrian. As far as this shell can locate the horizon, it is Cambrian, and probably low down in the Upper Cambrian, if not in the Middle Cambrian.

FORMATION AND LOCALITY.—**Passage beds** between the Upper Cambrian and the Ordovician: (309 [Moberg and Segerberg, 1906, desc. of Pl. I]) *Ceratopyge* limestone (Zone 4) at Fogelsång, 5 miles (8 km.) east of Lund, Province of Malmöhus, Sweden.

(323 [Wiman, 1902, p. 66]) *Phyllograptus* slate and *Ceratopyge* limestone in the Christiania region of Norway; and (323h [Brögger, 1882, p. 17]) blue *Ceratopyge* limestone at Vestfossen, 10 miles (16.1 km.) west-southwest of Christiania, Norway.

Upper Cambrian: (321e-321m [Wiman, 1902, p. 68]) Drift bowlders of *Ceratopyge* slate, Nos. 1-4, 6-8, 9, 12, 14, 17, 23, and 27, on Biludden, about 20 miles (32.2 km.) east of Gefle, Province of Gefleborg; and (321n [Wiman, 1902, p. 68]) drift bowlder of limestone (*Ceratopyge* slate horizon), at Trödje, in Gästrikland; both in Sweden.

(323a [Wiman, 1902, p. 66]) *Ceratopyge* slate in the Christiania region of Norway.

(318g [Davidson, 1868, p. 310]) Lower *Lingula* flags at Porth-y-rhaw, Pen-y-pleidiaw, and several other localities near St. Davids, South Wales.

(318c [Davidson, 1868, p. 310]) Lower *Lingula* flags at the Rheider Waterfall Valley and at Gwynfynydd and other places near Dolgelly, all in North Wales.

Middle? Cambrian (Probably between Middle and Upper Cambrian): (392g [Dawson, 1888a, p. 55]) Black shales at Little Metis, Province of Quebec, Canada.

Middle Cambrian: (2g) Sandstone of Division 1b1 of Matthew's [1895a, p. 108] *Protolenus* zone on Hanford Brook, St. John County; and (2s) limestone in upper part of *Paradoxides* zone, Hastings Cove [Matthew, 1898b, p. 38], on Kennebecasis Bay, 0.5 mile (0.8 km.) northeast of Torryburn, on the Intercolonial Railway northeast of St. John, St. John County; both in New Brunswick.

(6g) Limestone near the base of the Middle Cambrian, the lowest horizon carrying *Paradoxides*, northwest side of Chapple Arm Harbor, about 1 mile (1.6 km.) from its head, Trinity Bay; (6w) limestone at Seal Point Cove, near Long Point, Trinity Bay; and (6i) limestone about 300 feet (91.4 m.) below the base of the Upper Cambrian on shore north of Fosters Point, Random Island, Random Sound; all three in Newfoundland.

(318h) Shales in the Menevian at St. Davids, South Wales.

(316b [Davidson, 1883, p. 211]) Cairn Burn and Druidhill Burn, both in Dumfriesshire, Scotland.

(8w) Limestones of the *Paradoxides forchhammeri* zone, at Andrarum, 20 miles (32.2 km.) northwest of Simrishamn, Province of Christianstad; (321y) shale at Andrarum, 20 miles (32.2 km.) northwest of Simrishamn, Christianstad; and (321z) shales at Fogelsång, 5 miles (8 km.) east of Lund, Province of Malmöhus; all in Sweden.

(16l) Limestones of the *Paradoxides davidis* zone at Borregaard; (16i) limestones of the *Conocoryphe exsulans* zone at Borregaard; (16j) limestones of the *Paradoxides forchhammeri* zone at Laesaå; (16h and 334h) limestones of the *Paradoxides forchhammeri* zone at Borregaard; and (16k) limestones of the *Paradoxides davidis* zone at Laesaå; all on Bornholm Island, Denmark.

Specimens somewhat doubtfully compared with *Acrotreta sagittalis* occur at the following locality:

Middle Cambrian: (317a [Davidson, 1871, p. 340]) at Bellewstown, County Meath; and at Balbriggan, County Dublin; both in Ireland.

ACROTRETA cf. SAGITTALIS.

High up in the Middle Cambrian of the House Range, Utah, there is a small, depressed species of *Acrotreta* that appears to be identical with *A. sagittalis* as the latter occurs in Sweden and Newfoundland. Some of the ventral valves are very low, but specimens of a similar character occur in the limestones of Sweden and Newfoundland.

FORMATION AND LOCALITY.—**Middle Cambrian:** (11n) About 3,000 feet (914.4 m.) above the Lower Cambrian and 1,400 feet (426.7 m.) below the Upper Cambrian, in the upper part of the limestone forming 1a of the Marjum limestone [Walcott, 1908f, p. 179], in the long cliff southeast of Marjum Pass [Walcott, 1908f, Pls. XIII and XV], House Range, Millard County, Utah.

A somewhat similar shell that also strongly suggests *Acrotreta sagittalis* occurs in the Middle Cambrian limestones near Antelope Springs, in the House Range, Millard County, Utah. As the material is not very good or abundant, nothing more will be done at present toward identifying it.

ACROTRETA SAGITTALIS MAGNA (Matthew).

Plate LXVI, figures 4, 4a-f.

Linnarssonella belti magna MATTHEW, 1897, Trans. Roy. Soc. Canada for 1897, 2d ser., vol. 3, sec. 4, No. 7, pp. 169-170, Pl. I, figs. 1a-b. (Described and discussed as a new variety. The specimens represented by figs. 1a and 1b are redrawn in this monograph, Pl. LXVI, figs. 4b and 4-4a, respectively.)

Acrotreta sagittalis magna (Matthew), WALCOTT, 1902, Proc. U. S. Nat. Mus., vol. 25, pp. 595-596. (Discussed as below.)

In addition to the material collected by Matthew, I have a number of specimens collected by me at the typical locality at Hastings Cove. A comparison with a series of specimens of *Acrotreta sagittalis* (Salter) from St. Davids, Wales, and of *A. sagittalis transversa* (Hartt) shows at once that the form Matthew named is very closely related to both. The length and size of the median ridge, and the position of the central scars of the dorsal valve, and the size and position of the cardinal scars of the ventral valve are the internal characters that Matthew depends upon to distinguish the variety *magna*. All of the characters are fully covered by the variations in the same characters in *A. sagittalis* and its variety *transversa*. The nearly circular form of the variety *magna* is about the only character that can be considered of value, and that is very closely approached by some specimens of *A. sagittalis* (Pl. LXXI, figs. 3b, 3e, 3h).

It is not probable that the New Brunswick shell is a variety of *Acrotreta belti* (Davidson) (Pl. LXXVII). In order to have all the data possible for the student I have illustrated Matthew's types, which he kindly sent me for the purpose, also specimens I found in the limestone at the base of the beds carrying *Paradoxides* at Hanford Brook.

FORMATION AND LOCALITY.—**Middle Cambrian:** (2s)^a Limestones in upper part of *Paradoxides* zone, Hastings Cove [Matthew, 1898b, p. 38], on Kennebecasis Bay, 0.5 mile (0.8 km.) northeast of Torryburn, on the Intercolonial Railway, northeast of St. John; (2i) sandstones of Division 1b3 of Matthew's [1895a, p. 108] *Protolenus* zone, Hanford Brook; and (2l) limestones at base of *Paradoxides* zone, Hanford Brook; all in St. John County, New Brunswick, Canada.

^a 2s is the type locality, though the specimens in the United States National Museum collections to which that number is assigned were collected later than the type specimens.

ACROTRETA SAGITTALIS TACONICA (Walcott).

Plate LXXI, figures 1, 1a-o.

- Linnarssonia taconica* WALCOTT, 1887, Am. Jour. Sci., 3d ser., vol. 34, pp. 189-190, Pl. I, figs. 18, 18a-d. (Described and discussed as a new species. The specimens represented by figs. 18a-c are redrawn in this monograph, Pl. LXXI, figs. 1a, 1c, and 1h, respectively.)
- Linnarssonia taconica* Walcott, OEHLERT, 1889, Annuaire géologique universel for 1888, tome 5, p. 113S. (Described in French in a review of the preceding reference.)
- Linnarssonia sagittalis taconica* WALCOTT, 1889, Am. Jour. Sci., 3d ser., vol. 38, p. 36. (Stratigraphic position mentioned.)
- Linnarssonia sagittalis taconica* WALCOTT, 1891, Tenth Ann. Rept. U. S. Geol. Survey, pp. 610-611, Pl. LXVIII, figs. 1, 1a-d. (This description and the figures are copied from Walcott, 1887, p. 189, Pl. I, figs. 18, 18a-d.)
- Acrotreta sagittalis taconica* WALCOTT, 1902, Proc. U. S. Nat. Mus., vol. 25, pp. 596-597. (Characterized and discussed as below.)

This variety is characterized by the uniformly shorter median ridge of the dorsal valve. The ventral valve appears to be identical with those of *Acrotreta sagittalis* (Salter) from Andramur, which are embedded in the same character of matrix as the variety *taconica*.

This is the second representative of the genus found in association with the *Olenellus* fauna. *Acrotreta primæva* Walcott occurs in the upper zone of the *Olenellus* fauna in Nevada, and this is in the upper portion of the same fauna in the Appalachian region. Its association with *Microdiscus connexus*, a representative of *Microdiscus punctatus* of the *Paradoxides* zone of New Brunswick, also serves to connect it with *Acrotreta sagittalis*. It appears to be one of the few forms that connect the Atlantic Province Cambrian fauna with that of the Appalachian Province. It has been found in abundance in the Lower Cambrian of the Canadian Rocky Mountains, thus extending its range to the Cordilleran Province.

FORMATION AND LOCALITY.—Lower Cambrian: (36b) Limestone near schoolhouse No. 12, near Greenwich; (338g) limestone in the town of Greenwich; (33 and 338c) limestone at and near Rock Hill schoolhouse, near North Greenwich; (338e) limestone a little west of North Greenwich; (338f) limestone near Argyle, 8 miles (12.8 km.) north of Greenwich; (36 and 338d) limestone 1 mile (1.6 km.) south of Shushan; (338x) limestone 0.5 mile (0.8 km.) south of Coila, just east of Cambridge; (43a) limestone 1 mile (1.6 km.) east-northeast of Salem; (45a) limestone at McNaughton Corner, 1 mile (1.6 km.) east of Salem; and (37b) limestone 0.25 mile (0.4 km.) east of Salem; all in the Cambridge quadrangle (U. S. Geol. Survey), Washington County, New York.

(35) Limestones 1.5 miles (2.4 km.) north of Bald Mountain, 3.5 miles (5.6 km.) north-northwest of Greenwich; and (338h) limestone on the summit of Bald Mountain, about 2 miles (3.2 km.) northwest of Greenwich; both in the Schuylerville quadrangle (U. S. Geol. Survey), Washington County, New York.

(34) Limestone on roadside a little west of the bridge over Poultney River at Low Hampton, about 5 miles (8 km.) east-northeast of Whitehall; (39) limestone south of the Delaware and Hudson Railroad track on the road running south-southwest from Low Hampton, about 5 miles (8 km.) east-northeast of Whitehall; (45b) limestone near the roadside about 1,200 feet (366 m.) east of Bristol's house, near Low Hampton, about 5 miles (8 km.) east-northeast of Whitehall; and (338a) limestone in the northeast section of Whitehall township; all in the Whitehall quadrangle (U. S. Geol. Survey), Washington County, New York.

(20a) Gray limestone, interbedded with shaly slates, in a lane west of Lafayette Stevens's house, about 100 yards (91.4 m.) from the main road, in the southern part of Whitehall township; (22) limestone 1.5 miles (2.4 km.) north of North Granville; and (38a) limestone 2 miles (3.2 km.) south of North Granville, on the road which turns south from the road running between that village and Truthville, 4 miles (6.4 km.) west-northwest of Granville; all in the Fort Ann quadrangle (U. S. Geol. Survey), Washington County, New York.

(22a) Limestone in Penrhyn quarries, Middle Granville, Mettawee quadrangle (U. S. Geol. Survey), Washington County, New York.

(338b) Limestone on Kinderhook Creek near Stockport Paper Mill; (29) limestone just above the bridge at the Stockport Paper Mill, on Kinderhook Creek; (44b) limestone near North Chatham; and (32a) limestone 0.75 mile (1.2 km.) west of Riders Mills on the Harlem Extension Railroad, about 9 miles (14.4 km.) north-northeast of Chatham; all in the Kinderhook quadrangle (U. S. Geol. Survey), Columbia County, New York.

(44a) Limestone on Valatie Kill, near the line between Nassau and Schodack townships, near the line between the Troy and Kinderhook quadrangles (U. S. Geol. Survey); (338y) limestone north of Eagle Mills; (338) limestone at Schodack, northeast corner of the Cossackie quadrangle (U. S. Geol. Survey); and (29a) limestone 1 mile (1.6 km.) below the New York Central Railroad depot at Schodack; all in Rensselaer County, New York.

(58k) Just below the Middle Cambrian in limestones forming 1 of the Mount Whyte formation [Walcott, 1908c, p. 240 (9)]; (57m) about 50 feet (15 m.) below the Middle Cambrian in a siliceous shale correlated with 1b of the Mount Whyte formation on Mount Bosworth [Walcott, 1908f, p. 213]; (57e) about 115 feet (35 m.) below the Middle Cambrian, in limestone correlated with the top of 1c of the Mount Whyte formation on Mount Bosworth [Walcott, 1908f, p. 213]; (57r and 58s) about 150 feet (46 m.) below the Middle Cambrian, near the base of the limestones forming 3 of the Mount Whyte formation [Walcott, 1908c, p. 241 (10)]; and (35f) about 300 feet (91 m.) below the Middle Cambrian, in the limestone forming 6 of the Mount Whyte formation [Walcott, 1908c, p. 242 (11)]; all on Mount Stephen, just above the tunnel on the north shoulder, 3 miles (4.8 km.) east of Field, British Columbia.

(57s) About 160 feet (49 m.) below the Middle Cambrian, near the base of the gray oolitic limestone forming 1b of the Mount Whyte formation [Walcott, 1908f, p. 212], on Mount Bosworth, north of the Canadian Pacific Railway between Hector and Stephen, on the Continental Divide between British Columbia and Alberta, Canada.

ACROTRETA SAGITTALIS TRANSVERSA (Hartt).

Plate LXXII, figures 1, 1a-k.

- Obolella transversa* HARTT, 1868, *Acadian Geology*, by Dawson, 2d ed., p. 644. (Characterized.)
- Obolella transversa* HARTT, 1878, *idem*, 3d ed., p. 644. (Copy of preceding reference.)
- Obolella transversa* Hartt, WALCOTT, 1884, *Bull. U. S. Geol. Survey* No. 10, p. 16, Pl. 1, figs. 5 and 5a. (Original description copied and species discussed. The specimens represented by figs. 5 and 5a are not redrawn in this monograph, but better figures of them are given by Walcott, 1891a, Pl. LXVIII, figs. 2a and 2c, respectively.)
- Linnarssonina transversa* (Hartt), WALCOTT, 1885, *Am. Jour. Sci.*, 3d ser., vol. 29, p. 115, figs. 3, 4, 6, and 7, p. 116. (Discussed as the type of the new genus *Linnarssonina*. Figs. 3 and 7 are drawn from the specimens figured by Walcott, 1884a, Pl. I, figs. 5 and 5a, respectively.)
- Linnarssonina transversa* (Hartt), MATTHEW, 1886, *Trans. Roy. Soc. Canada* for 1885, 1st ser., vol. 3, sec. 4, No. 4, p. 35, Pl. V, figs. 11, 11a-e. (Discussed. Casts of the two specimens represented by figs. 11, 11a-e are figured by Walcott, 1891a, Pl. LXVIII, figs. 2d and 2a.)
- Obolella transversa* HARTT, 1891, *Acadian Geology*, by Dawson, 4th ed., p. 644. (Copy of Hartt, 1868, p. 644.)
- Linnarssonina sagittalis transversa* (Hartt), WALCOTT, 1891, *Tenth Ann. Rept. U. S. Geol. Survey*, Description of Pl. LXVIII, figs. 2a, 2c, and 2d. (No text reference. Figs. 2a and 2c are drawn from the specimens figured by Walcott, 1884a, Pl. I, figs. 5 and 5a, respectively. Fig. 2d is drawn from the specimen figured by Walcott, 1885a, fig. 6, p. 116. Figs. 2d and 2a are drawn from casts of the two specimens figured by Matthew, 1886, Pl. V, figs. 11, 11a-e.)
- Linnarssonina transversa* (Hartt), HALL and CLARKE, 1892, *Eleventh Ann. Rept. State Geologist New York* for 1891, Pl. III, figs. 22 and 23. (Fig. 22 is drawn from the specimen figured by Matthew, 1886, Pl. V, fig. 11.)
- Linnarssonina transversa* (Hartt), HALL and CLARKE, 1892, *Nat. Hist. New York*, *Paleontology*, vol. 8, pt. 1, p. 108, Pl. III, figs. 38-42. (Mentioned in the text. Figs. 38-39 and 40-42 are drawn from the specimens figured by Matthew, 1886, Pl. V, figs. 11c and 11, respectively. Figs. 42 and 39 are copied from figs. 22 and 23, respectively, of the preceding reference.)
- Linnarssonina transversa* (Hartt), MATTHEW, 1895, *Trans. New York Acad. Sci.* for 1894-95, vol. 14, p. 125, Pl. V, figs. 1a-c and 2a-c. (Locality mentioned. The figures are copied from Matthew, 1886, Pl. V, figs. 11, 11a-e.)
- Linnarssonina sagittalis transversa* (Hartt), FRECH, 1897, *Additional plates inserted in 1897 in Lethæa geognostica*, pt. 1, *Lethæa palæozoica*, Atlas, 1876, Pl. IA, fig. 3b. (No text reference. Fig. 3b is copied from Walcott, 1891a, Pl. LXVIII, fig. 2d.)

This is the representative of *Acrotreta sagittalis* (Salter) in the *Paradoxides* zone of New Brunswick. Many shells are more transverse in outline than the average of *A. sagittalis*, but examples of the latter (Pl. LXXI, figs. 3, 3a, 3g, 3j) are nearly as much so and the interior casts show a striking similarity in the Welsh and Acadian forms. The range of variation in each form is nearly as great as the variation between the two. In view of this, I think it is best to characterize *transversa* as a variety of *A. sagittalis*.

The shells from the "Protolenus beds" of Hanford Brook also vary in form from the nearly circular variety *magna* to the transverse forms included under *transversa*.

FORMATION AND LOCALITY.—Upper Cambrian: (3) Shales 300 feet (91.4 m.) above the *Paradoxides* zone, Manuels Brook, Conception Bay, Newfoundland.

Middle Cambrian: (2f and 2g) Sandstones of Division 1b1: (2h) overlying 2g in the sandstones of Division 1b2; (2) sandstones of Division 1b2; (2i) sandstones of Division 1b3; (2k) overlying 2i in the sandstones of Division 1b3; and (301b) sandstones of Division 1b5 and higher; all in Matthew's [1895a, p. 108] *Protolenus* zone, Hanford Brook, St. John County, New Brunswick.

(301c) Sandstones of the St. John formation, at Coldbrook; and (301k) St. John formation, in the city of St. John; both in St. John County, New Brunswick.

ACROTRETA SCHMALENSEEI Walcott.

Plate LXX, figures 1, 1a-s.

- Not *Acrotreta socialis* VON SEEBACH, 1865, Zeitschr. Deutsch. geol. Gesell. for 1865, Bd. 17, p. 341, Pl. VIIIA, figs. 1-4. (This species is referred in this monograph to *Acrotreta socialis*.)
- Acrotreta socialis* LINNARSSON [not VON SEEBACH], 1876, Bihang till K. svensk. Vet.-Akad. Handl., Bd. 3, No. 12, pp. 16-18, Pl. III, figs. 32-35. (Described and discussed in English.)
- ?*Acrotreta socialis* LINNARSSON, 1877, Geol. Fören. i Stockholm Förhandl., No. 40, Bd. 3, No. 12, p. 374. (Not figured, and may belong with either *Acrotreta schmalenseei* or *A. socialis*.)
- Acrotreta socialis* LINNARSSON, WALLERIUS, 1895, Undersökningar öfver Zonen med *Agnostus lævigatus* i Västergötland, p. 66. (Discussed in Swedish.)
- Acrotreta schmalensei* WALCOTT, 1902, Proc. U. S. Nat. Mus., vol. 25, pp. 597-598. (Described as below as a new species.)

As in the case of many other species of this genus, the student is referred to the series of figures illustrating it for information as to the external outline, form, and convexity of the two valves and the range of known variation. The collections of the United States National Museum contain a large series of specimens from which the shells illustrated were selected.

The broad false area has a shallow, faint median groove on some specimens, and on others no traces of it have been seen. The pedicle aperture, which is exceedingly minute, is situated at the extreme apex of the ventral valve; the cast of the base of the pedicle tube is clearly shown in interior casts of the valve (Pl. LXX, figs. 1f and 1h). One of the distinguishing characters is the cast of the large main vascular sinuses on each side of the visceral area, a feature which varies (Pl. LXX, figs. 1e, 1i, and 1s). The casts of the interior of the dorsal valve (figs. 1j-1p) are interesting and instructive in showing the considerable variation in the size and length of the median ridge, and the size of the cardinal and central scars.

The shell is small and built up of a thin outer layer and several inner layers or lamellæ more or less oblique to the outer layer. The outer surface is marked by fine concentric striæ and lines of growth, and the inner surfaces of the lamellæ by concentric striæ and fine radiating striæ. The average length of the opening of the valves is 1.5 to 2 mm., and the width is usually a little more.

Observations.—All of the specimens illustrated are from the *Paradoxides forchhammeri* zone. They appear to be identical with the figures of *Acrotreta socialis* given by Linnarsson [1876, Pl. III, figs. 32-35], but are not like those given by von Seebach [1865, Pl. VIIIA, figs. 1-4]. Those of the latter represent a shell with strong concentric striæ and median groove on the false area, characters that Linnarsson states that he did not find on his specimens. Among the collections made for me by Mr. G. Schmalensee, a collector in the Geological Survey of Sweden, I find a larger *Acrotreta* than the one described by Linnarsson [1876, p. 16], which agrees with the description of *A. socialis* given by von Seebach [1865, p. 341] and with his figures. Linnarsson writes that he thinks that von Seebach had representatives of several species before him when he wrote his notes on *A. socialis*. With this I fully agree, but with the collections now before me from Bornholm and Oeland, I think the specific name *A. socialis* should be given to the larger shell, illustrated by von Seebach [1865, Pl. VIIIA, figs. 1-4], and a new name given to the smaller and very distinct shell illustrated by Linnarsson [1876, Pl. III, figs. 32-35]. In recognition of the faithful and intelligent work of Mr. G. Schmalensee, I take pleasure in naming the species in his honor.

Acrotreta schmalenseei is of the type of *A. subconica* Kutorga, but is much less elevated. It may be compared with *A. microscopica* (Shumard) and *A. gemma* Billings among American species.

FORMATION AND LOCALITY.—**Middle Cambrian:** (323b) Limestone of the *Paradoxides ælandicus* zone, at Windjuelandet, Ringsaker, Province of Hedemerken, Norway.

(320n) Limestones of the *Paradoxides forchhammeri* zone at Lovened, Djupadal, 19 miles (30.6 km.) south-southeast of Skara; (320e) limestone at Munkesten, north of Hunneberg; (321q) limestones of the *Paradoxides forchhammeri* zone at Munkesten, north of Hunneberg; and (320m [Linnarsson, 1876, p. 18]) limestone of the *Paradoxides forchhammeri* zone at Kinnekulle, northeast of Lidköping; all in the Province of Skaraborg, Sweden.

(8w) Limestones of the *Paradoxides forchhammeri* zone at Andrarum; and (320c [Wallerius, 1895, p. 66]) Andrarum limestone, at Andrarum; both 20 miles (32 km.) northwest of Simrishamn, Province of Christianstad, Sweden.

(320d) *Ersulans* limestone in the lower part of the *Paradoxides tessini* zone, at Fogelsång, 5 miles (8 km.) east of Lund, Province of Malmöhus, Sweden.

(310c [Wallerius, 1895, p. 66]) Limestone of the *Paradoxides aelandicus* zone, on Oeland Island; (310p [Linnarsson, 1876, p. 18]) limestone of the *Paradoxides aelandicus* zone at Borgholm; and (310b) dark-brown limestone at Borgholm, on Oeland Island; all in Sweden.

(16j) Limestone of the *Paradoxides forchhammeri* zone at Laesaå; (16h) limestone of the same zone at Borregaard; and (334 [Wallerius, 1895, p. 66]) limestone of the *Paradoxides forchhammeri* zone; all on Bornholm Island, Denmark.

ACROTRETA SEEBACHI Walcott.

Plate LXXVII, figures 3, 3a.

Acrotreta seebachi WALCOTT, 1902, Proc. U. S. Nat. Mus., vol. 25, pp. 598-599. (Described and discussed as below as a new species.)

Acrotreta seebachi Walcott, MOBERG and SEGERBERG, 1906, Medd. från Lunds Geol. Fältklubb, Ser. B, No. 2 (Afttryck ur K. Fysiografiska Sällskapets Handl., N. F., Bd. 17), pp. 66-67. (Characterized and discussed in Swedish.)

Among the fragments of trilobites in the *Ceratopyge* limestone collected by Schmalensee there are a few specimens of a species of *Acrotreta* distinct from *A. schmalenseei* Walcott and *A. socialis* von Seebach. The ventral valve is relatively low, with the false area nearly vertical. A cast of this valve shows the cardinal scars on each side high up toward the apex; small main vascular sinuses and apical callosity. False area rather large and marked by a slight indication of a median depression that is recognized by a slight undulation in the transverse striæ. Surface marked by fine threadlike concentric striæ and lines of growth. A broken dorsal valve has a broad median sulcus and a small distinct beak at the posterior margin. The valves are slightly transverse. A large ventral valve measures 3 mm. in width by 2.5 mm. in length.

The surface striæ and the cardinal scars serve to distinguish this species from others known to me. *Aerothèle? ceratopygarum* (Brögger) is from the *Ceratopyge* shales, but it has a low ventral valve with the false area sloping forward.

After deciding that a new species was represented in the material received from Schmalensee, I studied a fine series of specimens that Dr. W. C. Brögger kindly sent me. In material collected by Schmalensee from the *Ceratopyge* shale at Borgholm, Oeland Island, Sweden, some imperfect specimens suggest *Acrotreta seebachi*; they might equally well be referred to *A. carinata* Moberg and Segerberg, or *A. circularis* Moberg and Segerberg.

The specific name was given in honor of Dr. K. von Seebach.

FORMATION AND LOCALITY.^a—**Passage beds** between the Upper Cambrian and the Ordovician: (8x) *Ceratopyge*, limestone at Slemmestad, about 3 miles (4.8 km.) southwest of Christiania; (323d) *Ceratopyge* limestone (Étage 3a₇ of Brögger) at Christiania; (323f) lower part of the *Ceratopyge* limestone [Brögger, 1882, pp. 16 and 17] at Vestfossen, 10 miles (16.1 km.) west-southwest of Christiania; (323h) blue *Ceratopyge* limestone [Brögger, 1882, p. 17] at Vestfossen, 10 miles (16.1 km.) west-southwest of Christiania; and (323e) *Ceratopyge* limestone at Engervik, near Christiania; all in Norway.

Upper Cambrian: (310d) *Ceratopyge* slate at Borgholm, Oeland Island, Sweden.

Specimens somewhat doubtfully referred to this species occur at the following locality:

Passage beds between the Upper Cambrian and the Ordovician: (323g) *Ceratopyge* limestone (Étage 3a₇ of Brögger), at Vaekkerö, in the Christiania region, Norway.

ACROTRETA SHANTUNGENSIS Walcott.

Plate LXIX, figures 5, 5a-e.

Acrotreta shantungensis WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 301-302. (Described and discussed as below as a new species.)

Shell small. Ventral valve a low cone with the apex a little forward of the posterior margin, which is slightly flattened; apex minute, directed backward and projecting slightly over the faintly defined false area. The cast of the interior shows that the apical callosity was rather large and that the main vascular sinuses were well defined on each side of it; the cardinal scars are small and not prominent.

^a Localities 8x and 310d are represented in the collections of the United States National Museum; the others are in the collection of the University of Christiania.

Dorsal valve slightly convex; apex marginal; surface marked by a rather broad, shallow median depression that begins on the umbo and gradually widens toward the front margin. The interior of the dorsal valve has a strong median ridge extending from the posterior margin two-thirds the distance toward the front. A small, elevated cardinal scar occurs on each side of the median ridge a little in advance of the posterior margin. Main vascular sinuses rather strong; they start beneath the apex and extend forward a short distance from the outer lateral margin of the shell.

Surface marked by fine concentric striæ and lines of growth.

Observations.—This shell in size and general form is closely related to *Acrotreta microscopica* (Shumard) (Pl. LXVII) of the Middle Cambrian fauna of the United States.

The specific name is derived from Shantung, China.

FORMATION AND LOCALITY.—**Middle Cambrian:** (C37) Upper part of the Kichou limestone^a in dense black limestone nodules in green-gray shales 10 feet (3 m.) below the base of the cliff limestone, 8 miles (12.8 km.) south of Ting-hianghien; and (C71) massive cliff-making limestone in the central portion of the Kichou formation [Willis and Blackwelder, 1907, pp. 139 and 145 (2d list of fossils)], 4 miles (6.4 km.) southwest of Tungyu, Shansi, China.

(C1) Lower shale member of the Kiulung group [Blackwelder, 1907a, pp. 37 and 40 (part of the 3d list of fossils), and fig. 10 (bed 4), p. 38], 2 miles (3.2 km.) south of Yenchuang; and (C62) *early layer in the middle limestone member of the Kiulung group* [Blackwelder, 1907a, pp. 37 and 40 (last list of fossils), and fig. 10 (base of bed 7), p. 38], 2.5 miles (4 km.) south of Yenchuang, on the north-northeast spur of Hulushan; both in the Sintai district, Shantung, China.

A shell apparently identical with *Acrotreta shantungensis* was collected at the following locality:

Middle Cambrian: (C32) A fine-grained, bluish-black limestone boulder believed to have come from the lower part of the Kisinling limestone [Blackwelder, 1907b, p. 272], collected in river drift 1 mile (1.6 km.) south of Chon-pinghien, on Nankiang River, southern Shensi, China.

ACROTRETA SIGNALIS Walcott.

Plate LXIX, figure 4.

Acrotreta signalis WALCOTT, 1902, Proc. U. S. Nat. Mus., vol. 25, p. 599. (Described and discussed as below as a new species.)

Ventral valve transverse, broadly ovate; height about one-third the length; apex directed backward on a line with the posterior margin, which is transverse and slightly undulated at the center by the median furrow of the false area; apex with a minute apical foramen which is directed backward. Surface marked by fine concentric striæ and lines of growth that at the median furrow of the false area curve toward the posterior margin.

Shell small, 1.5 mm. long by about 1.75 mm. in width. Shell built up of several very thin layers or lamellæ.

Observations.—In all of the extensive collections made from the Cambrian sandstones of the upper Mississippi Valley, only two ventral valves of any species of *Acrotreta* have been found, as far as known to me. These occur in association with *Lingulella (Lingulepis) acuminata* (Conrad) and the shells have the color and appearance of those of that species, shiny light gray to white, the original coloring matter having been leached out. Only the exterior of the ventral valve is known. This compared with *A. microscopica* (Shumard) (Pl. LXVII) shows a less elevated ventral valve and a less distinct false area. It also has a marked median groove on the false area. It recalls *A. idahoensis* Walcott, but differs in being more depressed and in having a stronger groove on a narrower false area.

FORMATION AND LOCALITY.—**Middle Cambrian:** (328e) "St. Croix sandstone" at St. Croix Falls, Polk County, Wisconsin.

ACROTRETA SOCIALIS von Seebach.

Plate LXXIII, figures 3, 3a-c, 4, 4a-e.

Acrotreta socialis VON SEEBACH [NOT LINNARSSON], 1865, Zeitschr. Deutsch. geol. Gesell. for 1865, Bd. 17, p. 341, Pl. VIIIa, figs. 1-4. (Described and discussed in German, as a new species. Figs. 1-4 are reproduced in this monograph, Pl. LXXIII, figs. 3, 3a-c, respectively.)

^a The fossils from this locality are not listed, but the presence of Cambrian strata at the locality is mentioned by Willis and Blackwelder [1907, p. 146].

- Not *Acrotreta socialis* LINNARSSON, 1876, Bihang till K. svensk. Vet.-Akad. Handl., Bd. 3, No. 12, pp. 16-18, Pl. III, figs. 32-35. (Described and discussed in English. This species is referred in this monograph to *Acrotreta schmalenseei*.)
- ?*Acrotreta socialis* LINNARSSON, 1877, Geol. Fören. i Stockholm Förhandl., No. 40, Bd. 3, No. 12, p. 374. (Not figured, and may belong with either *Acrotreta socialis* or *Acrotreta schmalenseei*.)
- Acrotreta socialis* von Seebach, WALCOTT, 1902, Proc. U. S. Nat. Mus., vol. 25, pp. 599-600. (Described and discussed essentially as below.)
- Not *Acrotreta* cf. *socialis* MATTHEW, 1902, Bull. Nat. Hist. Soc. New Brunswick, vol. 4, pt. 5, No. 20, pp. 392-394, Pl. XV, figs. 5a-k. (Described and discussed. This species is referred in this monograph to *Acrotreta* sp. undt.)
- Not *Acrotreta* cf. *socialis* MATTHEW, 1903, Geol. Survey Canada, Rept. Cambrian Rocks Cape Breton, pp. 183-185, Pl. III, figs. 5a-k. (Copy of preceding reference. This species is referred in this monograph to *Acrotreta* sp. undt.)

The species described and illustrated by von Seebach [1865, p. 341, Pl. VIIIa, figs. 1-4] as *Acrotreta socialis* is characterized by a well-marked, concentrically striated surface and a strong median groove in the false area. In the collections made for me by Mr. Schmalensee at Borg-holm, Oeland Island, I find associated with *Paradoxides ælandicus* an *Acrotreta* that has these characters. All the specimens from the *Paradoxides forchhammeri* zone in the large collection before me, with the exception of one ventral valve, belong to a distinct species which I have named *A. schmalenseei*. Von Seebach evidently had specimens of the latter species, also of a species of *Acrotreta* from the *Ceratopyge* limestone, as he mentions the occurrence of *A. socialis* at both horizons.

The external form, as far as known to me, is shown by the figures. There is some variation in the height of the ventral valve and in the outline of the margins of the valves. The false area is clearly defined and marked by a strong, rather broad median groove. The pedicle aperture is at the apex of the ventral valve and quite readily seen in several specimens, a character in strong contrast with the minute aperture at the apex of *A. schmalenseei* Walcott. Shell formed of several thin layers or lamellæ that show very plainly where the thin outer layer is exfoliated. Surface marked by striæ and lines of growth that are very distinct on some shells and less so on others; the concentric striæ occur on all the lamellæ of the shell and on the inner surface; fine radiating striæ are to be found on the inner surface. The cast of the interior of the ventral valve shows the presence of a large apical callosity and unusually large pedicle tube and main vascular sinuses on each side of the visceral cavity. The cardinal scars are well defined in both the ventral and dorsal valves. Casts of the interior of the dorsal valve show a strong median ridge, central scars, and fairly well-defined main vascular sinuses. Von Seebach [1865, p. 341] describes the surface as having minute warts on it. I find numerous fragments of the shell of *Acrothele* (*Redlichella*) *granulata* (Linnarsson) associated with *Acrotreta socialis*, and it may be that von Seebach mistook the surface of this shell for that of the species he was describing. No known species of *Acrotreta* has such a surface.

A large ventral valve has a diameter of 5 mm. and a height of 2.5 mm. The average size is about 3 mm. in diameter.

A single ventral valve found by Schmalensee at Andrarum appears to belong to this species. It is a cast of the interior of the shell, and shows concentric ridges or undulations of growth, well-defined cardinal scars, large apical callosity, and short but strong main vascular sinuses (Pl. LXXIII, fig. 4b).

This species belongs to the *A. subconica* Kutorga group of species with a broad false area and well-defined median groove. Its surface is more strongly marked by concentric striæ than any other species of the genus, and the shell is also thicker.

Grönwall [1902, p. 39] and Linnarsson [1877, p. 374] refer specimens to *Acrotreta socialis*, but do not accompany the references by descriptions or figures, and I therefore can not decide whether to include the forms with *Acrotreta socialis* or *Acrotreta schmalenseei*.

Matthew [1902b, p. 392] has compared some imperfect specimens of a species of *Acrotreta* from McNeil Brook, Cape Breton, with *Acrotreta socialis* von Seebach. The shells, as far as can be determined, do not belong to this species. They are about the same size, but the ventral valve is depressed and more like that of *Acrotreta sagittalis magna* (Matthew). I can not identify

the species with the material available for study, and I have entered it in this monograph as *Acrotreta* sp. undt. (see p. 715).

FORMATION AND LOCALITY.—**Middle Cambrian:** (8z) Limestones of *Paradoxides ælandicus* zone, Borgholm, Oeland Island; (320n) limestones of the *Paradoxides forchhammeri* zone at Lovened, Djupadal, 19 miles (30.6 km.) south-south-east of Skara, Province of Skaraborg; and (8w) limestones of *Paradoxides forchhammeri* zone at Andrarum, 20 miles (32.2 km.) northwest of Simrishamn, Province of Christianstad; all in Sweden.

(334g [Seebach, 1865, pp. 340 and 341]) Limestones on Bornholm Island, Denmark.

ACROTRETA SPINOSA Walcott.

Plate LXXIX, figures 4, 4a-g.

Acrotreta spinosa WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 302. (Characterized as below, as a new species.)

The general form of this shell is much like that of *Acrotreta idahoensis* Walcott (Pl. LXVIII, figs. 2, 2a-g). It differs in having a straighter posterior margin. The distinguishing character of the species is the spinose outer surface. The surface is marked by fine concentric lines of growth at irregular intervals, with numerous, very fine, threadlike striæ between. On some shells occur radiating, more or less irregular, fine, rounded ridges that are formed by the elevated elongate spine bases. When these elongate bases are irregularly arranged the radiating ridges are not present. Owing to their minute size, the spinules are rarely seen.

FORMATION AND LOCALITY.—**Upper Cambrian:** (65) Limestone on east side of Sierra Canyon, opposite Pinnacle Peak; (62a) limestone on east side of Sierra Canyon, opposite the Jackson mine; (62) limestone in the Dunderberg shale [Walcott, 1908f, p. 184], in canyon immediately north of Adams Hill; and (61) limestone in the Dunderberg shale [Walcott, 1908f, p. 184], a little south of the Hamburg mine; all in the Eureka district [Hague, 1892, Atlas], Eureka County, Nevada.

ACROTRETA SUBCONICA Kutorga.

Plate LXXIII, figures 2, 2a-i.

Acrotreta subconica KUTORGA [not MEEK], 1848, Verhandl. Russ.-kais. min. Gesell. St. Petersburg for 1847, No. 12, p. 275, Pl. VII, figs. 7a-c. (Described in German as a new species; see below for translation. Figs. 7a, 7b, 7c, 7b', and 7c' are reproduced in this monograph, Pl. LXXIII, figs. 2, 2a-d, respectively. The specimens represented by figs. 7a, 7b', and 7c' are redrawn in this monograph, Pl. LXXIII, figs. 2e, 2h, and 2i, respectively. Figs. 2f and 2g on Pl. LXXIII of this monograph represent one of Kutorga's type specimens, but he figured only the dorsal valve, 1848, Pl. VII, fig. 7c'.)

Acrotreta MORRIS, 1849, Annals and Mag. Nat. Hist., 2d ser., vol. 4, Pl. VII, figs. 4a-b. (No text reference. Figs. 4a and 4b are copied from Kutorga's figures, 1848, Pl. VII, figs. 7b' and 7c', respectively, of *Acrotreta subconica*.)

Acrotreta subconica KUTORGA, DAVIDSON, 1853, British Fossil Brachiopoda, vol. I, Introduction, No. 3, Pl. IX, figs. 271-275. (No text reference. Figs. 271-275 are copied from Kutorga, 1848, Pl. VII, figs. 7c, 7a, 7b, 7b', and 7c', respectively.)

Acrotreta subconica KUTORGA, VON SEEBACH, 1865, Zeitschr. Deutsch. geol. Gesell. for 1865, Bd. 17, p. 341. (Mentioned in discussion of *A. socialis*.)

Not *Acrotreta subconica* MEEK, 1873, Sixth Ann. Rept. U. S. Geol. Survey Territories for 1872, p. 463. (This species is referred in this monograph to *Acrotreta idahoensis*.)

Acrotreta subconica KUTORGA, QUENSTEDT, 1885, Handbuch der Petrefactenkunde, Aufl. 3, p. 755, Pl. LVIII, fig. 51. (Mentioned. Fig. 51 is roughly copied from Kutorga, 1848, Pl. VII, fig. 7b.)

Acrotreta subconica KUTORGA, WALCOTT, 1902, Proc. U. S. Nat. Mus., vol. 25, pp. 600-601. (Original description translated and type specimens discussed as below.)

The original description by Kutorga follows:

Strongly conical; the deltidium-like furrow narrow and plainly impressed. Innumerable growth wrinkles run on the whole surface of the shell horizontally, and make deflections only in the furrow, the convexity of which is turned toward the base of the cone.

Height of the cone, 0.014; length of the base of the ventral valve, 0.012; breadth of the same, 0.015.

Four specimens, of which one is complete and three are without ventral valve. From the collection of Herr von Volborth.

On one specimen with the apex broken off I investigated the surface of the fracture under the microscope, with a magnification of forty-five times, and found on it two cruriform, shallow impressions similar to those on the casts of the Siphonotretes. Their surface was polished and with impressions of growth folds, and between the extremities of the crura, in the neighborhood of the area-like hinge surface, a columniform fragment of the mold of the siphon. From this it follows that the broken-off tip, just as the beak of the Siphonotretes, was solid and contained a cylindrical siphon.

Observations.—Through the courtesy and permission of Dr. Fr. Schmidt, Dr. Fr. von Huene kindly sent me the types of this species, which he had been studying. One of them preserves the outer shell at the apex. It shows a minute foraminal aperture on the back side of the apex and a strong median groove on the false area. The outlines of the pedicle valve vary from the somewhat diagrammatic drawings of Kutorga [1848, Pl. VII, figs. 7a-c], and there is some variation among the five specimens representing the types. The characters of the shell are shown by the figures on Plate LXXIII.

FORMATION AND LOCALITY.—Ordovician: (336) *Echinospharites* limestone, horizon C1a [Fr. Schmidt, personal communication, 1906], Popowka, near St. Petersburg, Russia.

ACROTRETA ULRICHI Walcott.

Plate LXXVIII, figure 3.

Acrotreta ulrichi WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 3, pp. 96-97, Pl. IX, fig. 3. (Described and discussed as below as a new species. Fig. 3 is copied in this monograph, Pl. LXXVIII, fig. 3.)

This species is founded on a single specimen of a finely preserved ventral valve. The outline of the aperture is nearly circular, except for a short transverse portion beneath the false area; surface moderately convex, with the apex curving and ending beyond the posterior margin so that the minute foraminal aperture opens backward; a small false area is indicated by a slight incurving at the cardinal angles; the area is without traces of a median furrow.

Surface of shell marked by very fine, concentric striæ and lines of growth. Length and width of aperture 2 mm.; convexity of ventral valve 1 mm.

Observations.—This species is characterized by its curved umbo and apex, and overhanging false area. It most nearly resembles *A. curvata* Walcott, from which it differs in being less convex, and in the form of its umbo and curved apex.

The specific name was given in honor of Mr. E. O. Ulrich.

FORMATION AND LOCALITY.—Upper Cambrian: (12p) About 225 feet (69 m.) above the igneous rocks, in the limestones of the Reagan sandstone, at the northwestern extremity of the Arbuckle Mountains, about 4 miles (6.4 km.) east of Homer, Carter County, Oklahoma.

ACROTRETA UPLANDICA Wiman.

Plate LXX, figures 3, 3a-c.

Acrotreta uplandica WIMAN, 1902, Bull. Geol. Inst. Univ. Upsala, vol. 6, pt. 1, No. 11, p. 54, Pl. II, figs. 15-18. (Described in German as a new species. The specimens represented by figs. 15-18 are redrawn in this monograph, Pl. LXX, figs. 3, 3a-c, respectively.)

Acrotreta uplandensis (Wiman), WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 302. (Characterized as below.)

This species recalls at once *Acrotreta idahoensis sulcata* Walcott. It differs from it in having a broader false area. The surface is marked by fine, threadlike striæ that cross the false area and false pedicle groove.

FORMATION AND LOCALITY.—Middle? Cambrian: (311b) *Drift boulder of gray bituminous sandstone, No. 2* [Wiman, 1902, p. 57], on *Biludden*, about 20 miles (32.2 km.) east of Gefle, Province of Gefleborg; and (311p) *drift boulder of glauconitic sandstone, No. 1* [Wiman, 1902, p. 57], at Högånäs, parish of Börstil, east of Östhammar, Province of Stockholm; both in Sweden.

ACROTRETA UPLANDICA LIMÖENSIS (Wiman).

Plate LXX, figures 4, 4a-c.

Acrotreta limöensis WIMAN, 1902, Bull. Geol. Inst. Univ. Upsala, vol. 6, pt. 1, No. 11, p. 54, Pl. II, figs. 19-22. (Characterized in German as a new species. The specimens represented by figs. 19-22 are redrawn in this monograph, Pl. LXX, figs. 4, 4a-c, respectively.)

Acrotreta uplandica limonensis (Wiman); WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 303. (Characterized as on p. 715.)

Wiman states [1902, p. 54] that this form is quite like *Acrotreta uplandica*, but lower, as the height is only one-third of the diameter. It is so close in all other respects that I do not think that more than a varietal value should be given to the differences mentioned.

The specific name is derived from Limön Island, Sweden.

FORMATION AND LOCALITY.—Middle? Cambrian: (311n) Drift bowlder of bluish calcareous sandstone, No. 6 [Wiman, 1902, p. 57], on Limön Island, about 12 miles (19.3 km.) east-northeast of Gefle, Province of Gefleborg, Sweden.

ACROTRETA sp. undt.

Acrotreta cf. *socialis* MATTHEW [not LINNARSSON or VON SEEBACH], 1902, Bull. Nat. Hist. Soc. New Brunswick, vol. 4, pt. 5, No. 20, pp. 392-394, Pl. XV, figs. 5a-k. (Described and discussed.)

Acrotreta cf. *socialis* MATTHEW, 1903, Geol. Survey Canada, Rept. Cambrian Rocks Cape Breton, pp. 183-185, Pl. III, figs. 5a-k. (Copy of preceding reference.)

Matthew describes and illustrates this form and compares it with *Acrotreta socialis* von Seebach. A comparison of his specimens with *A. socialis* shows the two forms to be distinct. Matthew's specimens are more suggestive of *A. sagittalis magna* (Matthew) (Pl. LXVI, figs. 4, 4a-f) except that the ventral valve is higher.

With the original specimens for study it appears best to indicate this form as an undetermined species.

FORMATION AND LOCALITY.—Middle Cambrian: (325a [Matthew, 1903, p. 184]) Shales of Division C2c of Matthew's Bretonian, on the eastern slope of the valley of McNeil Brook, on the road to Trout Brook, Cape Breton, Nova Scotia.

ACROTRETA sp. undt. Westergård.

Acrotreta sp. WESTERGÅRD, 1909, Medd. från Lunds Geol. Fältklubb, Ser. B, No. 4 (Aftryck ur K. Fysiografiska Sällskapets Handl., N. F., Bd. 20), pp. 57 and 77, Pl. II, figs. 25a-b. (Locality mentioned in Swedish.)

This species is not described by Westergård, and I have not seen the specimen. It is of medium height and appears to be a true *Acrotreta*.

FORMATION AND LOCALITY.—Upper Cambrian: (310t) Subzone c of the *Dictyograptus* slate at Fogelsång; (310u) subzone c of the *Dictyograptus* slate at Jerrestad; and (310v) subzone b of the *Dictyograptus* slate at Tosterup; all Westergård, 1909, pp. 57 and 77] in the Province of Malmöhus, Sweden.

Genus ACROTHYRA Matthew.^a

[ἄκρος, at the top; and θύρα, a door.]

Acrothyra MATTHEW, 1901, Bull. Nat. Hist. Soc. New Brunswick, vol. 4, pt. 4, No. 19, pp. 303-304. (Described and discussed as a new genus.)

Acrothyra MATTHEW, 1902, Trans. Roy. Soc. Canada for 1902, 2d ser., vol. 8, sec. 4, No. 3, p. 104. (Notes on variation in size, etc., of the different species and varieties of *Acrothyra*.)

Acrothyra MATTHEW, 1903, Geol. Survey Canada, Rept. Cambrian Rocks Cape Breton, pp. 85-86. (Copied from Matthew, 1901b, pp. 303-304.)

Acrothyra MATTHEW, 1903, idem, pp. 88-89. (Copied from Matthew, 1901b, p. 304.)

Acrothyra MATTHEW, WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 4, Pl. XI, and pp. 142 and 146. (Classification of genus.)

Ventral valve elongate conical, with the posterior face more or less flattened to form a false area marked on the median line by a shallow groove. Area unknown. The slope of the false area is usually backward so as to throw the apex back of the posterior margin, but in some instances it is directly on a line with the margin. Pedicle opening minute, slightly truncating the apex. Dorsal valve strongly convex with the beak marginal. Area unknown.

Surface marked by fine, concentric striæ and lines of growth and very fine, irregular, concentric striæ that inosculate so as to give a granulose or pitted surface when seen by a strong lens. The inner surface of the ventral valve shows fine radiating lines in some specimens. The shell is built up of several thin layers or lamellæ of a calcareoconchous character. The

^a The synonymy for this genus does not give a complete record of the various genera under which the species now included in *Acrothyra* were formerly placed; it gives only those references in which the genus is discussed or described. To complete the record the following mere generic references are listed: *Acrotreta* Matthew [1899b, p. 203; 1902b, pp. 390 and 391; 1903, pp. 73 and 95].

dorsal valve is usually thicker than the ventral valve, and its inner lamellæ are arranged more oblique to the outer layer.

The cast of the ventral valve indicates a small apical callosity penetrated by a slender pedicle tube. The main vascular sinuses are almost straight from the apex far out toward the anterolateral portion of the valve; in the short valves they diverge quite rapidly, but in the elongated valves they leave but a narrow space for the visceral area. From the anterior margin of the apical callosity two narrow ridges extend well forward and then curve outward and inward to meet about a central depression or pit that occupies the same relative position as the central depression of the visceral cavity in *Obolus* and its subgenera. The cardinal scars have not been observed. The interior of the dorsal valve is strongly concave. A slight median ridge is seen in some specimens and in others it is very difficult to determine its presence except in the posterior third of the shell, where it is often very strong. On each side of the median ridge there is usually a rather deep groove in which, at about one-third the distance from the posterior to the front margins of the valve, the central muscle scars occur; the cardinal scars are clearly defined on each side of the median ridge near the posterior margin.

Type.—*Acrotreta proavia* Matthew.

Observations.—This genus is intimately related to *Acrotreta* and except for the presence in some species of a well-marked visceral area of a type not known in *Acrotreta* there would be difficulty in assigning more than a subgeneric value to it. Matthew [1901b, p. 303] considers that the mode of occurrence of the ventral valve indicates a difference from *Acrotreta*, but in the large collection made by Loper the ventral valve of *Acrothyra* lies on the long side of the cone, the aperture being up; this is the position the shell would take in settling down on the bottom when the animal was out of the shell and the dorsal valve detached. I have found hundreds of specimens of the ventral valve of *Acrotreta idahoensis* Walcott and *A. attenuata* Meek lying on the upper surface of layers of limestone in situ, in just the same positions as those taken by *Acrothyra proavia* (Matthew).

Four species of the genus are known to me: *Acrothyra proavia* (Matthew), *A. signata* Matthew, *A. sera* (Matthew), and *A. minor* Walcott. Matthew [1902a, pp. 381–390] has described a number of varieties of the two Acadian species. In the case of the varieties of *A. proavia* I find that there is such a gradation of form and character between the varieties that they are of little value. In *A. signata* the varieties *prima* and *orta* are apparently distinctive.

After a thorough comparison of Matthew's types of *Acrothyra signata sera*, *Acrothyra signata tarda*, *Acrotreta papillata* and varieties *prima* and *lata*, and a large series of specimens from the same locality and stratigraphic horizon, I have identified the four forms as *Acrothyra sera*. There is such a gradation in size and shape of the visceral area and exterior of the ventral valve that it does not appear practicable to draw lines establishing varieties and species. The gradation of characters between Matthew's *Acrothyra signata sera* and his *Acrotreta papillata* also practically brings together *Acrothyra* and *Acrotreta*. An attempt is made on Plate LXXX to show some of the gradations in the form of the visceral area (figs. 6d, 6e, 5a, 6f, 6g, 6h, and 6a).

Matthew [1902a, p. 381] assigns importance to the stratigraphic position of the specimens he has referred to species and varieties. This does not appear to hold good in the large collections made by Loper. Most of the varieties in form and robustness occur at the horizon of *Acrothyra sera* and those assigned to *A. proavia* at its horizon. This makes it difficult to give the same importance to the variations that Matthew [1902a, pp. 381–390] does in his descriptions. The latter are presented in great detail and should be consulted by those interested in this genus or in the Acrotretidæ.

Matthew [1901c, pp. 93–107] has made some most interesting and suggestive observations on the resemblance of the more elongated forms of *Acrothyra* to some species of *Hyolithes*, suggestions to which the student of the Brachiopoda should give careful consideration.

ACROTHYRA MINOR Walcott.

Text figure 59; Plate LXXVI, figures 4, 4a-b.

Acrothyra minor WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 303. (Characterized as below as a new species.)

This species differs from others referred to the genus by its broad form and very strong vascular sinuses. The elevated callus between the sinuses is high and oval in outline, somewhat like that of *Acrotreta inflata* (Matthew). It may be that this species belongs to a different genus, but with the material available for study it is referred to *Acrothyra* on account of its low overhanging false area and elongate visceral area.

FORMATION AND LOCALITY.—Middle Cambrian: (5b and 54s)^a Dark blue-gray Langston limestone [Walcott, 1908f, p. 198], just above the Cambrian quartzitic sandstones, north side of Twomile Canyon, near its mouth, 2 miles (3.2 km.) southeast of Malade, Oneida County, Idaho.

ACROTHYRA PROAVIA (Matthew).

Plate LXXV, figure 3; Plate LXXVI, figures 3, 3a-u.

Acrotreta proavia MATTHEW, 1899, Bull. Nat. Hist. Soc. New Brunswick, vol. 4, pt. 3, No. 19, p. 203, Pl. III, figs. 2a-f. (Described and discussed as a new species.)

Acrothyra proavia prima MATTHEW, 1901, idem, vol. 4, pt. 4, No. 19, figs. 1-6, p. 303. (No mention of this species is made in the text, which is a description of the genus *Acrothyra*, but the variety is figured for the first time. The specimen represented by fig. 1 is redrawn in this monograph, Pl. LXXVI, fig. 3.)

Acrothyra proavia MATTHEW, 1902, idem, vol. 4, pt. 5, No. 20, pp. 386-388, Pl. XIV, figs. 2a-g and 3a-f. (Described and discussed. Figs. 2a-f are copied from Matthew, 1899, Pl. III, figs. 2a-f.)

Acrothyra proavia prima MATTHEW, 1902, idem, p. 389, Pl. XIV, figs. 4a-f. (Described. Figs. 4a-f are copied from Matthew, 1901b, figs. 1-6, p. 303.)

Acrothyra proavia crassa MATTHEW, 1902, idem, pp. 389-390, Pl. XIV, figs. 5a-c. (Described and discussed as a new variety.)

Acrothyra proavia MATTHEW, 1903, Geol. Survey Canada, Rept. Cambrian Rocks Cape Breton, pp. 53-55, 57, and 59. (Notes on orientation of shells.)

Acrothyra proavia prima MATTHEW, 1903, idem, p. 58. (Notes on orientation of shells.)

Acrothyra proavia prima MATTHEW, 1903, idem, figs. 1-6, p. 86. (Figs. 1-6 are copied from Matthew, 1901b, figs. 1-6, p. 303.)

Acrothyra proavia prima MATTHEW, 1903, idem, p. 93, Pl. II, figs. 4a-f. (Text and figures copied from Matthew, 1902a, p. 389, Pl. XIV, figs. 4a-f.)

Acrothyra proavia crassa MATTHEW, 1903, idem, p. 94, Pl. II, figs. 5a-c. (Text and figures copied from Matthew, 1902a, pp. 389-390, Pl. XIV, figs. 5a-c.)

The generic description is founded on this species and gives all of its principal characters. Matthew refers to several varieties of this species and [1901b, p. 303, and 1902a, p. 389] names two of them, *prima* and *crassa*. Loper's collection shows a great variation in the form and outline of the valves, particularly the ventral, that appears to include the varieties described by Matthew. The typical form of *A. proavia* is illustrated by Plate LXXVI, figures 3a, 3b, and 3c; the variety *prima* by figure 3, and the variety *crassa* by figures 3e and 3f. The gradations in form between the typical form and its varieties may be traced by the figures on the plate, and by a study of the large series of specimens in the collections.

The height of the posterior side or false area has been found one-third, one-half, and about three-fifths of the length of the anterior slope from the apex to the margin. The wide variation appears to be due very largely to compression and distortion in the sediment.

Acrotreta gemmula Matthew occurs in association with this species, and this leads to confusion of the dorsal valves of the two species unless care be taken to distinguish them. The *A. gemmula* shells are rare, and the shell is thinner, which gives less strongly marked interiors, and less convexity to the outer surface. The dorsal valve of *Acrothyra proavia* is convex, strong, and deeply marked by the grooves made by the main vascular sinuses.

FIGURE 59.—*Acrothyra minor* Walcott. A, A', Exterior and side views of a ventral valve from Locality 54s, about 2 miles (3.2 km.) southeast of Malade, Idaho (U. S. Nat. Mus. Cat. No. 52051).

^a5b is the type locality.

Acrothyra proavia differs from *A. signata* Matthew, which occurs about 200 feet lower in the strata of the same section, in having usually a narrower, more elongate visceral cavity, and stronger callosity. These features, however, vary in specimens of *A. proavia* associated in the same hand specimen of shale.

FORMATION AND LOCALITY.—Middle Cambrian: (3i) Compact, fine-grained, thin-bedded gray sandstone of the *Paradoxides* zone, on McLean Brook, 1 mile (1.6 km.) east of McCodrum Brook and 1.5 miles (2.4 km.) west of Marion Bridge; (13m) sandstones of Division E3f of Matthew's [1903, p. 76] Etcheminian, on Gillis Brook, Indian River; and (344j [Matthew, 1903, p. 91]) Division E3e of Matthew's Etcheminian, on the highway at V. McPhees; all in eastern Cape Breton, Nova Scotia.

(10p) Sandstone just below the waterfall in Dugald Brook, Division E2b; (10q) sandstones a little above 10p in Division E2b; (13e) sandstones of Division E2c; (131 and 344i [Matthew, 1903, p. 80]) sandy shales of Division E3a; (13n'' and 344b [Matthew, 1903, p. 91]) sandstones of Division E3d; (13n') sandstones of Division E3e; (344a [Matthew, 1903b, p. 422]) sandy shales of Division E3c; and (344d [Matthew, 1903, p. 82]) sandy shales of Division E3f; all in Matthew's [1903, p. 21] Etcheminian, on Dugald Brook, Indian River, eastern Cape Breton, Nova Scotia.

ACROTHYRA SERA (Matthew).

Plate LXXX, figures 4, 4a-c, 5, 5a-d, 6, 6a-i, 7, 7a-b, 8?.

Acrothyra (signata) sera MATTHEW, 1902, Bull. Nat. Hist. Soc. New Brunswick, vol. 4, pt. 5, No. 20, pp. 383-384, Pl. XIII, figs. 3a-f. (Described and discussed as a new variety. The specimen represented by fig. 3c is redrawn in this monograph, Pl. LXXX, fig. 4c.)

Acrothyra signata-tarda MATTHEW, 1902, idem, pp. 384-385, Pl. XIV, figs. 1a-d. (Described and discussed as a new variety.)

Acrotreta papillata MATTHEW, 1902, idem, pp. 390-391, Pl. XV, figs. 2a-f. (Described as a new species. In the description of Pl. XV the legend for figs. 1a-c appears as the legend for figs. 2a-c, and the legend for figs. 2a-f as the legend for figs. 1a-f; the specimens represented by figs. 1a-c (on the plate) are referred to *Acrotreta papillata prima*; and the specimens represented by figs. 2a-f (on the plate) are referred to *Acrotreta papillata*. The description of plate is in error, the correct reference being as given in this synonymy. The specimen represented by figs. 2a and 2b is redrawn in this monograph, Pl. LXXX, figs. 6 and 6'.

Acrotreta papillata var. MATTHEW, 1902, idem, p. 391, Pl. XV, figs. 3a-c. (Described. The varietal name *lata* is given to this form in the description of Pl. XV.)

Acrotreta papillata-prima MATTHEW, 1902, idem, pp. 391-392, Pl. XV, figs. 1a-c. (Described and discussed as a new variety. The third reference explains error in description of plate.)

Acrothyra signata sera MATTHEW, 1903, Geol. Survey Canada, Rept. Cambrian Rocks Cape Breton, p. 56. (Notes on the orientation of the shells.)

Acrotreta papillata-prima MATTHEW, 1903, idem, pp. 73-74, Pl. III, figs. 1a-c. (Mentioned as a new variety, but copies the original text and figures, Matthew, 1902a, pp. 391-392, Pl. XV, figs. 1a-c. The same error occurs in the description of Pl. III as occurred in the description of Pl. XV; see the third reference.)

Acrothyra signata sera MATTHEW, 1903, idem, pp. 87-88, Pl. I, figs. 3a-f. (Text and figures copied from Matthew, 1902a, pp. 383-384, Pl. XIII, figs. 3a-f.)

Acrothyra signata-tarda MATTHEW, 1903, idem, p. 89, Pl. II, figs. 1a-d. (Text and figures copied from Matthew, 1902a, pp. 384-385, Pl. XIV, figs. 1a-d.)

Acrotreta papillata MATTHEW, 1903, idem, p. 95, Pl. III, figs. 2a-f. (Text and figures copied from Matthew, 1902a, pp. 390-391, Pl. XV, figs. 2a-f. The same error occurs in the description of Pl. III as occurred in the description of Pl. XV; see the third reference.)

Acrotreta papillata lata MATTHEW, 1903, idem, pp. 95-96, Pl. III, figs. 3a-c. (Text and figures copied from Matthew, 1902a, p. 391, Pl. XV, figs. 3a-c.)

Acrothyra sera differs from *A. signata* in the form of the visceral area and callosity, straighter and nearly vertical posterior side. It is usually more elongate. Matthew [1902a, p. 383] placed it as a variety of *A. signata*, but its characters appear to justify giving it the rank of a species.

A gradation in length, breadth, depth, and outline of the ventral valve and its visceral area is found in specimens from the same bed of rock, that bring together *Acrothyra signata sera* and *tarda* and *Acrotreta papillata* and its varieties *lata* and *prima*. Matthew [1902a, pp. 383-385, 390-392] based the above-mentioned species and varieties on differences in form of the ventral valve and its visceral cavity and callosity. With his type specimens before me, and the large series of specimens collected by Loper from Matthew's Division 1, assise d, and from Division 2, between assise a and b, it is impossible for me to consider that more than one variable species is represented. As the name *sera* is first in order in the original publication, it is retained for the species. Also see notes under genus *Acrothyra*, pages 715-716.

FORMATION AND LOCALITY.—**Middle Cambrian:** (10p′) Sandstone 0.25 mile (0.4 km.) from the lower bridge on Gregwa Brook, Indian River; (10p′′) sandstone on the small brook on the hill between the bridge over Indian River and McPhees Brook; (13k) shales of Matthew's [1903, p. 15] Coldbrook, above the great fall in Dugald Brook, Indian River; and (344e [Matthew, 1903, p. 78]) shales of Division E1d of Matthew's [1903, pp. 28 and 29] Etcheminian, on Boundary Brook, eastern side of the Escasonie Indian Reservation; all in eastern Cape Breton.

(344g [Matthew, 1903, p. 77]) Shales of Division E1c; (13t′′) sandstones of Divisions E1c and E1d; (13f) sandstones 20 feet (6 m.) above Division E2a; (13d′) sandstones opposite the third waterfall in Dugald Brook, between Divisions E2a and E2b; (10p) sandstones just below the waterfall in Division E2b; and (13e) sandstones of Division E2c; all in Matthew's [1903, p. 21] Etcheminian, on Dugald Brook, Indian River, eastern Cape Breton, Nova Scotia.

Shells somewhat doubtfully referred to *Acrothyra sera* occur at the following localities:

Middle Cambrian: (13p) Sandstones 40 feet (12.2 m.) above Division E2a; and (13p′) sandstones 45 feet (13.6 m.) above Division E2a; both in Matthew's [1903, p. 21] Etcheminian, on Dugald Brook, Indian River, eastern Cape Breton, Nova Scotia.

ACROTHYRA SIGNATA Matthew.

Plate LXXX, figures 1, 1a-d.

Acrothyra signata MATTHEW, 1902, Bull. Nat. Hist. Soc. New Brunswick, vol. 4, pt. 5, No. 20, pp. 381-382, Pl. XIII, figs. 2a-e. (Described and discussed as a new species, see below for copy of the greater part. The specimens represented by figs. 2h and 2c are redrawn in this monograph, Pl. LXXX, figs. 1 and 1d, respectively.)

Acrothyra signata MATTHEW, 1903, Geol. Survey Canada, Rept. Cambrian Rocks Cape Breton, p. 87, Pl. I, figs. 2a-e. (Text and figures copied from preceding reference.)

Matthew's description [1902a, p. 381] of the interior of the two valves is as follows:

There is a strong narrow callus, one-third of the length of the valve, bounded by a raised ridge at the sides and in front; at the front of this callus is an oval pit, from which a groove runs backward nearly to the apex of the shell, where it is supposed to connect with the foramen. Outside the callus, on each side, near the margin of the valve, are lenticular marks of the lateral muscles. About the middle of the valve the position of the anterior adductors is indicated by a faint impression of the lozenge or "heart-shaped" depression. * * *

* * * This shows a sharp, thin, median septum for half of the length of the valve. This ridge is broader and more distinct at the front; at each side are lateral obscure ridges, diverging from the umbo. Outside of these ridges are the lenticular imprints of the lateral muscles.

The only modification to be made is in leaving out the word "narrow" before "callus" in the description of the ventral valve. The callosity is strong and relatively broad.

Among the type specimens received from Doctor Matthew one ventral valve is elongate, like the type figured by him. Two other ventral valves are shorter, like our figures 1, 1a-b. The dorsal valves are similar in the material received from Doctor Matthew and that illustrated by him, and in the collection made by Mr. S. Ward Loper.

A. signata differs from *A. proavia* (Matthew) in the less elongate, narrow visceral cavity and apical callosity of the ventral valve. It occurs at about 200 feet lower in the strata, according to Matthew, who [1903, pp. 23-27] gives a detailed section of the beds and lists of fossils occurring at each faunal zone.

Matthew [1902a, p. 382] found this species in his Division E1b. Loper collected it from Matthew's Division E1d; also in abundance between Divisions E2a and E2b on Dugald Brook.

FORMATION AND LOCALITY.—**Middle Cambrian:** (13t) Sandstones at the base of Division E1b; (344k [Matthew, 1903, p. 77]) sandstones of Division E1b; (13t′′) sandstones of Divisions E1c and E1d; (13d′) sandstones opposite the third waterfall in Dugald Brook, between Divisions E2a and E2b; (10p) sandstones just below the waterfall in Division E2b; all in Matthew's [1903, p. 21] Etcheminian, Dugald Brook, Indian River, eastern Cape Breton, Nova Scotia.

ACROTHYRA SIGNATA ORTA Matthew.

Plate LXXX, figures 3, 3a-b.

Acrothyra signata orta MATTHEW, 1902, Bull. Nat. Hist. Soc. New Brunswick, vol. 4, pt. 5, No. 20, pp. 385-386, Pl. XIII, figs. 4a-f. (Described and discussed as a new variety. The specimens represented by figs. 4a and 4c are redrawn in this monograph, Pl. LXXX, figs. 3a and 3b, respectively.)

Acrothyra signata orta MATTHEW, 1903, Geol. Survey Canada, Rept. Cambrian Rocks Cape Breton, pp. 89-90, Pl. I, figs. 4a-f. (Text and figures copied from the preceding reference.)

A. signata orta differs from *A. signata* Matthew in its more elongate form and narrow visceral area, characters that place the variety near *A. proavia* (Matthew). Its shorter visceral area distinguishes it from *A. proavia*. In the absence of specimens showing the interior of the ventral valve there is no way of distinguishing *A. proavia* from *A. signata orta*.

FORMATION AND LOCALITY.—Middle Cambrian: (13d'') Sandstones 10 feet (3 m.) below Division E2a; (10p) sandstones just below the waterfall in Division E2b; and (3441 [Matthew, 1903, p. 90]) sandstones of Division E2c; all in Matthew's [1903, p. 21] Etcheminian, Dugald Brook, Indian River, eastern Cape Breton, Nova Scotia.

ACROTHYRA SIGNATA PRIMA Matthew.

Plate LXXX, figures 2, 2a-b.

Acrothyra signata prima MATTHEW, 1902, Bull. Nat. Hist. Soc. New Brunswick, vol. 4, pt. 5, No. 20, pp. 382-383, Pl. XIII, figs. 1a-g. (Described and discussed as a new variety. The specimens represented by figs. 1b and 1c are redrawn in this monograph, Pl. LXXX, figs. 2 and 2b, respectively.)

Acrothyra signata prima MATTHEW, 1903, Geol. Survey Canada, Rept. Cambrian Rocks Cape Breton, p. 73, Pl. I, figs. 1a-g. (Text and figures copied from the preceding reference.)

The material representing this shell is in poor condition, but sufficient evidence of the form and interior characters of the ventral valve is preserved to show that it differs from *A. signata* Matthew in its subconical form, and in the shorter and proportionally broader visceral area. It is very difficult to find any clearly defined distinction between some specimens of *Acrothyra sera* Matthew and *A. signata prima*, as the latter shows ventral valves quite as regularly conical as the former. One of Matthew's type specimens shows a much higher apex on the ventral valve than his figure 3c [1903, Pl. I]; another with the apex broken off shows a cast of the visceral cavity much like that in Plate LXXX, figure 1a (*A. signata* Matthew).

Matthew [1902a, p. 383] found the types of this species in a fine gray shale interbedded in the volcanic beds. The associated fossils clearly indicate that the fauna is essentially the same as that which follows higher in the strata.

FORMATION AND LOCALITY.—Middle Cambrian: (13k) ^a Shales of Matthew's [1903, p. 15] Coldbrook, above the great waterfall in Dugald Brook, Indian River, Cape Breton, Nova Scotia.

Genus DISCINOPSIS Matthew.^b

[δίσκος, quoit; and ὤψ, face.]

Discinopsis (MATTHEW MS.) HALL and CLARKE, 1892, Eleventh Ann. Rept. State Geologist New York for 1891, pp. 250-251. (Described.)

Discinopsis Matthew, HALL and CLARKE, 1892, Forty-fifth Ann. Rept. New York State Museum for 1891, pp. 566-567. (Copy of preceding reference.)

Discinopsis Matthew, HALL and CLARKE, 1892, Nat. Hist. New York, Paleontology, vol. 8, pt. 1, pp. 105-106. (Described and discussed as a new genus.)

Discinopsis Matthew, WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 4, Pl. XI, and pp. 142 and 146. (Classification of genus.)

All that is known of this genus is incorporated under the description of the type species.

Type.—*Acrotreta? gulielmi* Matthew.

DISCINOPSIS GULIELMI (Matthew).

Plate LXXXII, figures 5, 5a-c.

Acrotreta? gulielmi MATTHEW, 1886, Trans. Roy. Soc. Canada for 1885, 1st ser., vol. 3, sec. 4, No. 4, pp. 37-39, Pl. V, figs. 14, 14a-e. (Described and discussed as a new species; see below for copy. The specimen represented by figs. 14c and 14d is redrawn in this monograph, Pl. LXXXII, fig. 5. Figs. 5a-c of this monograph are drawn from specimens in the type material, but none of them can be identified with Matthew's figures.)

Discinopsis gulielmi (Matthew), HALL and CLARKE, 1892, Eleventh Ann. Rept. State Geologist New York for 1891, Pl. III, figs. 20 and 21. (Fig. 20 is drawn from the specimen figured by Matthew, 1886, Pl. V, figs. 14c and 14d. Fig. 21 is drawn from one of Matthew's type specimens, and the same specimen is redrawn in this monograph, Pl. LXXXII, fig. 5a, but the specimen can not be identified with any of Matthew's figures.)

Discinopsis gulielmi (Matthew), HALL and CLARKE, 1892, Nat. Hist. New York, Paleontology, vol. 8, pt. 1, p. 105, Pl. III, figs. 20-24. (Discussed. Figs. 20 and 21 are copied from figs. 20 and 21 of the preceding reference. The remaining figures are drawn from specimens in Matthew's type material. Figs. 21, 22, and 23 represent specimens which are redrawn in this monograph, Pl. LXXXII, figs. 5a (= 21 and 22) and 5c (= 23), but it is impossible to identify the specimens with Matthew's figures.)

The original description by Matthew follows:

Shell subcircular in outline. Surface depressed-conical, apices eccentric, not marginal. Pedicle valve with the apex truncated by a circular foraminal aperture (?). The interior of this valve is characterized by a pair of deep,

^a 13k is the type locality, though the specimens represented by that number in the United States National Museum collections were collected later than the type specimens.

^b Prior to the definition of the genus *Discinopsis* the type species was referred to *Acrotreta?* [Matthew, 1886, p. 37].

diverging furrows, passing forward from the beak or internal foraminal opening, in broad curves which converge toward the anterior margin but without meeting. These furrows inclose a thickened and somewhat elevated central area, which, in the subumbonal region, is apparently free, projecting for a short distance, like a narrow, triangular shelf, beneath which the foramen probably opened. The interior opening of the foramen is, however, not apparent on any of the specimens examined, for, as usually preserved, the matrix has adhered to this subapical cavity, and in a single example only is the shelf-like character of the median area distinctly demonstrated. A faint longitudinal ridge passes from the apex of the shelf to the anterior margin, but no other markings are discernible on the interior—except faint radiating or slightly undulating, probably vascular lines.

The interior of the brachial valve, as far as known, shows no other characters than the radiating lines, which appear to belong to the ornamentation of the outer surface.

Shell substance tenuous, apparently corneous. External surface covered with more or less prominent, sometimes lamellose concentric growth lines, crossed by fine, gently curved, radiating striæ which are usually more prominent when the concentric lines are exfoliated.

Observations.—The interior of the ventral valve of this species is not unlike that of *Acrothele*. (Compare Pl. LXXXII, fig. 5a, with Pl. LX, figs. 1f and 2.) It is not like that of *Acrotreta sagittalis taconica* (Pl. LXXI). I have not been able to find an apical shelf in the type specimens or other specimens. The material representing *D. gubielmi* is compressed in the shale, so that the apical callosity is more or less compressed and distorted. The dorsal valve, with its eccentric apex, is unlike *Acrothele* or any other of the genera of the Acrotretidæ.

With our present information, *Discinopsis* is referred to the Acrotretidæ and nearest to *Acrothyra*.

I have not discussed the description and conclusions of Matthew [1886, p. 37], as neither Hall and Clarke nor I could find the muscle scars described and illustrated by him. The student should carefully read Matthew's description and observations, as there is much opportunity for difference of opinion of minute shells compressed in shale.

FORMATION AND LOCALITY.—Middle Cambrian: (301g [Matthew, 1886, p. 39] Sandstones of Division 1c of Matthew; (308h) shales of Division 1c1; and (301w) shales of Division 1c2; all at Portland (now part of the city of St. John), St. John County, New Brunswick.

DISCINOPSIS? SULCATUS Walcott.

Plate LXXXII, figure 6.

Craniella ?? sp., WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 29, pp. 4 and 6. (Listed.)

Discinopsis sulcatus WALCOTT, 1906, idem, vol. 30, pp. 568-569. (Described and discussed as below as a new species.)

This species is based upon the cast of the interior of a small ventral valve that in its interior markings closely approaches the interior of the ventral valve of *Discinopsis gubielmi* (Matthew).

The interior cast shows that the ventral valve was subcircular in outline, moderately convex, and with the apex probably perforated by a small, circular, foraminal aperture. In front of the cast of the base of the foraminal aperture there is a broad depression that extends to the front margin; on each side of the central depression an elongate, slightly depressed area extends forward and outward from near the base of the cast of the foraminal aperture, along the ridge on each side of the median depression; back of the base of the foraminal aperture there is a narrow, short, arched furrow that indicates the presence of a corresponding ridge on the interior of the shell. No other markings are shown on the cast, except the faint outline of what may have been the visceral area, on the median line in front of the base of the foraminal aperture and between the broad vascular sinuses.

Observations.—This species is referred to the genus *Discinopsis* as the result of comparison with specimens of the interior of a ventral valve of *D. gubielmi* (Matthew). One interior of the latter species has scars much like those shown in *D.?* *sulcatus*.

This form has a sulcate ventral valve, hence the specific name.

FORMATION AND LOCALITY.—Upper Cambrian: (C56) Lower part of the Chaumitien limestone, 25 feet below the top of Pagoda Hill [Blackwelder, 1907a, p. 42 (part of last list of fossils)], 1 mile (1.6 km.) west of Tsinan, Shantung, China.

Superfamily DISCINACEA Waagen.

Family DISCINIDÆ Gray.

Genus ORBICULOIDEA d'Orbigny.

For synonymy, description, and discussion of this genus the student is referred to the memoir of Hall and Clarke [1892c, pp. 120-137]. The genus has been recently classified [Walcott, 1908e, Pl. XI, and pp. 142 and 147].

Two Upper Cambrian species are tentatively referred to the genus: *O. varians* (Barrande) and *O. contraria* (Barrande), and one Middle Cambrian species, *O. pileolus* (Salter).

ORBICULOIDEA CONTRARIA (Barrande).

Plate LXXXI, figure 9.

Discina contraria BARRANDE, 1868, Faune silurienne des environs de Hof, en Bavière, p. 104, fig. 72. (Described in French as a new species; see below for translation. Fig. 72 is copied in this monograph, Pl. LXXXI, fig. 9.)

Genre? sp. *nebulosa* BARRANDE, 1868, idem, pp. 105-106, fig. 69. (Described and discussed in French as a new species.)

Discina contraria BARRANDE, 1868, Neues Jahrb. für Mineralogie für 1868, pp. 692-693, unnumbered plate, fig. 72. (Copied from Barrande, 1868a, p. 104, fig. 72.)

Genre? sp. *nebulosa* BARRANDE, 1868, idem, pp. 693-694, unnumbered plate, fig. 69. (Copied from Barrande, 1868a, pp. 105-106, fig. 69.)

Discina contraria Barrande, POMPECKJ, 1896, Tremadoc Fossilien bei Hof, p. 4. (Occurrence mentioned in German.)

The original description by Barrande follows:

This form, decidedly transverse, contrasts with the preceding, which is elongated. It also forms an ellipse, which, however, is truncated on the larger side. The shell presents only a slight bulge. The summit is placed somewhat beyond the center, going toward the truncated edge. Starting from the summit, the surface forms an inclined plane up to the contour. The perforation is linear and very short. The shell, partly preserved, presents very marked concentric striae, at unequal intervals.

Longitudinal diameter, 6 mm.; transverse diameter, 9 mm.

Observations.—Pompeckj [1896a, p. 4] states that this species was found much more frequently than *O. varians* (Barrande), and that rather convex shells, 10 mm. long and 12 mm. broad, were not rare.

The generic relation of this species is doubtful. It is not *Discina*, nor from the evidence available can it be referred without question to *Orbiculoidea*.

Pompeckj, in reply to my inquiry as to whether he had identified "Genre? *nebulosa*" of Barrande, wrote as follows under date of August 7, 1906:

As to the *nebulosa* by Barrande (Faune silurienne des Environs de Hof, fig. 69) I find in notes made on the Barrande originals (in the collection of the Oberbergamt-Munich) that "*nebulosa*" is to be identified with Barrande's *Discina contraria*, l. c., figure 72. Both are pedicle valves of *Discina* with the characteristic perforation of that family below the apex. Both figures are incorrectly given. The two sharp lines radiating from the apex in figure 69 are only caused by pressure of the somewhat high shell, and in figure 72 the concentric striae are indeed much more delicate than in the figures which represent an interior cast only, with bits of the shell in the upper part, i. e., near the hinge line.

Exact determination of these shells is very difficult; most of them (I saw more than a hundred) are compressed, crumpled, deformed, very seldom the apical region is clearly to be seen; shell rarely preserved; but there is indeed no doubt that they must belong to the Discinidæ on account of the "Schlitz" below the apex. There is no sharp difference between the rounded form, named *Discina varians* by Barrande, and between the larger and wider form, *D. contraria*, or *nebulosa*.

FORMATION AND LOCALITY.—Passage beds between the Upper Cambrian and the Ordovician: (303c [Barrande, 1868a, p. 104] suburbs of Hof; and (303f [Pompeckj, 1896a, pp. 7 and 8] railway cut near Schellenberg, a little distance back of the railway station at Neuhof, near Hof; both in Bavaria, Germany.

ORBICULOIDEA PILEOLUS (Hicks MS.) (Salter).

Plate LXXXI, figures 11, 11a.

Discina pileolus (Hicks MS.) SALTER, 1866, Rept. British Assoc. Adv. Sci. for 1865, p. 285. (Mentioned.)

Discina pileolus Salter, DAVIDSON, 1868, Geol. Mag., vol. 5, pp. 312-313, Pl. XVI, figs. 11-12. (Described and discussed; see p. 723 for copy of description. Figs. 11a and 12a are copied in this monograph, Pl. LXXXI, figs. 11 and 11a, respectively.)

- Discina pileolus* Salter, DAVIDSON, 1871, British Fossil Brachiopoda, vol. 3, pt. 7, No. 4, p. 344, Pl. XLIX, figs. 41-42. (Original description, Davidson, 1868, pp. 312-313, copied. Figs. 41 and 42 are copied from Davidson, Pl. XVI, figs. 12 and 11, respectively.)
- Not *Discina pileolus*? HICKS, 1871, Quart. Jour. Geol. Soc. London, vol. 27, pt. 1, Pl. XV, figs. 12 and 12a. (Referred in this monograph to *Stenotheca*.)
- Orbiculoidea pileolus* (Salter), HALL and CLARKE, 1892, Nat. Hist. New York, Paleontology, vol. 8, pt. 1, p. 137. (Changes generic reference.)

The original description by Davidson [1868, p. 312], follows:

Shell very small, circular or slightly longitudinal oval, rather broader anteriorly; about two and a half lines in length and a little less in breadth. Dorsal valve conical. Ventral valve slightly convex, depressed near the margin; vertex in both valves at a short distance from the center, as also the foramen (?) in the ventral valve. Surface marked with concentric lines, which are more strongly marked in the ventral valve. Interior not known.

I have not been able to secure specimens of this interesting shell, so can not add any personal observations upon it. Hall and Clarke [1892c, p. 137] suggest its reference to *Orbiculoidea* and in this, from our present information, I concur. As they have pointed out, it is the oldest representative of the genus.

Hicks [1871, Pl. XV, fig. 12] illustrates a depressed conical shell from the "Red" beds at the base of the "Purple" rocks, about 3,000 feet below the base of the Middle Cambrian "Menevian group" as "*Discina pileolus*." Later [1881, p. 297] he calls the species "*Discina cærfaiensis*." To me the shell is more suggestive of the gastropod genus *Stenotheca* than of a brachiopod and until I can obtain better material it will be so referred.

FORMATION AND LOCALITY.—Middle Cambrian: (318e) Lower portion of the Menevian at Camlan, North Wales; (318d) sandstones in the middle portion of the Menevian at Porth-y-rhaw, St. Davids, South Wales; (318p) sandstones in the middle portion of the Menevian at Ninewells, near St. Davids, South Wales; (318q) yellowish-gray beds in the Harlech group, on the road between Solva and Whitechurch, St. Davids, South Wales; and (318r) sandstones in the middle portion of the Menevian at Solva Harbor, St. Davids, South Wales; all [Davidson, 1871, pp. 344 and 345] in Wales.

ORBICULOIDEA VARIANS (Barrande).

Plate LXXXI, figure 8.

- Discina varians* BARRANDE, 1868, Faune silurienne des environs de Hof, en Bavière, pp. 103-104, fig. 71. (Described in French as a new species. Fig. 71 is copied in this monograph, Pl. LXXXI, fig. 8.)
- Discina varians* BARRANDE, 1868, Neues Jahrb. für Mineralogie für 1868, p. 692, unnumbered plate, fig. 71. (Copy of preceding reference.)
- Discina varians* Barrande, POMPECKJ, 1896, Tremadoc Fossilien bei Hof, p. 4. (Occurrence mentioned in German.)

The original description by Barrande follows:

The form of this species is always elongated, but in proportions varying somewhat with the individuals. The surface is slightly arched. The summit is somewhat beyond the center of the figure, which is an ellipse, slightly truncated at the small end near the perforation. The perforation is linear and less than 1 mm. in length. The fragments of the shell that remain present traces of fine concentric striae. The imperforate valve has not been observed. Length, 6 mm.; breadth, 5 mm.

Observations.—I am not able to add to the above description. It is evident that the species is not a *Discina*, as that genus is now understood, but with only a single figure and the above description it is not practicable to make a satisfactory generic reference. The subcentral apex with the elongate slit back of it, is more suggestive of *Orbiculoidea* than any other genus of the lower Paleozoic fauna.

FORMATION AND LOCALITY.—Passage beds between the Upper Cambrian and the Ordovician: (303c [Barrande, 1868a, p. 103]) suburbs of Hof; and (303f [Pompeckj, 1896a, pp. 7 and 8]) railway cut near Schellenberg, a little distance back of the railway station at Neuhof, near Hof; both in Bavaria, Germany.

Superfamily CRANIACEA Waagen.

Family CRANIIDÆ King.

Genus PHILHEDRA Koken.^a

Philhedra KOKEN, 1889, Neues Jahrb. für Mineralogie, Beilage-Band 6, Hft. 3, p. 465. (Discussed in German as a new genus.)

Philhedra Koken, VON HUENE, 1899, Neues Jahrb. für Mineralogie, Bd. 1, pp. 146-147. (Described and discussed in German. See below for translation of diagnosis.)

Philhedra Koken, VON HUENE, 1899, Verhandl. Russ.-kais. min. Gesell. St. Petersburg, 2d ser., Bd. 36, Lief. 2, pp. 216-218 (list of species referred to *Philhedra*), and pp. 297-298. (Described and discussed in German.)

Philhedra Koken, WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 4, Pl. XI, and pp. 142 and 147. (Classification of genus.)

The emended diagnosis of the species by von Huene follows:

Inequivalve, with the flat ventral shell attached. Dorsal shell subconical to bowl-shaped, frequently irregularly bent; the concentric growth lines are mostly crossed by radial ribs or rows of prickles; without limbus. Anterior oclusors larger than posterior oclusors.

Type.—*Patella rivulosa* Kutorga.

Von Huene, in his memoir on the Silurian Craniidæ [1899b, pp. 181-359], redefines the genus *Philhedra* of Koken, and considers *P. columbiana* (Walcott) as its oldest representative. The student who wishes to pursue the study further should read von Huene's memoir on the Silurian Craniidæ [1899b, pp. 181-359] and his "Systematik der Craniaden" [1899a, pp. 138-151].

PHILHEDRA COLUMBIANA (Walcott).

Plate LXXXI, figure 10.

Crania? columbiana WALCOTT, 1889, Proc. U. S. Nat. Mus. for 1888, vol. 11, p. 441. (Described and discussed as a new species.)

Crania? columbiana Walcott, VON HUENE, 1899, Neues Jahrb. für Mineralogie, Bd. 1, p. 141, footnote. (Mentioned.)

Philhedra? columbiana (Walcott), VON HUENE, 1899, Verhandl. Russ.-kais. min. Gesell. St. Petersburg, 2d ser., Bd. 36, Lief. 2, pp. 216 and 298. (Mentioned.)

Crania columbiana Walcott, MATTHEW, 1902, Trans. Roy. Soc. Canada for 1902, 2d ser., vol. 8, sec. 4, No. 3, pp. 108-109. (Copies the original description, Walcott, 1889c, p. 441.)

Philhedra columbiana WALCOTT, 1908, Canadian Alpine Journ., vol. 1, No. 2, Pl. I, figs. 5 and 5a. (No text reference. Figs. 5 and 5a are copied in this monograph, Pl. LXXXI, figs. 10 and 10', respectively.)

Shell small, subcircular, or a little longer than wide, subconical with the apex slightly eccentric. Outer surface exfoliated; the inner layer of the shell appears to have been composed of a calcareoconeous substance; it is marked by from 40 to 45 fine ribs that radiate from the apex to the margin. Diameter about 2 mm. When preparing this monograph I carefully examined the original specimen, removed a little of the attached matrix from the outer margins and discovered traces of what appear to be minute spines radiating from the margin.

Many collections from the type locality of this species have passed through my hands from 1888 to 1906, but it was not until the summer of 1907 that another specimen was seen, and then only two were found in the *Ogygopsis* zone of Mount Stephen. These are both crushed and broken specimens of the inner side of the conical valve. There is a striking similarity in appearance between this shell and *Crania lælia* Hall and Clarke [1892c, Pl. IV H, fig. 1] and other similar forms.

The specific name is derived from British Columbia.

FORMATION AND LOCALITY.—Middle Cambrian: (14s) About 2,300 feet (701 m.) above the Lower Cambrian and 2,700 feet (823 m.) below the Upper Cambrian, in the *Ogygopsis* zone of the Stephen formation [Walcott, 1908f, p. 210], on the northwest slope of Mount Stephen, above Field on the Canadian Pacific Railway, British Columbia, Canada.

^a The synonymy for this genus is not complete and does not even give a record of all the genera under which the Cambrian species of *Philhedra* has been placed; it gives only those references in which the genus is discussed or described. To complete the record for the species taken up in this monograph the following mere references are listed:

Crania? Walcott [1889c, p. 441].

Crania? von Huene [1899a, p. 141].

Crania Matthew [1902c, p. 108].

Order PROTREMATA Beecher.

[πρό, early; and τρήμα, perforation.]

Superfamily ORTHACEA Walcott and Schuchert.

Family BILLINGSSELLIDÆ Schuchert.

Subfamily NISUSIINÆ Walcott and Schuchert.

Genus NISUSIA Walcott.^a

Billingsella HALL and CLARKE (in part), 1892, Nat. Hist. New York, Paleontology, vol. 8, pp. 230-231. (Described and discussed as a new genus. As described the genus includes species that are now referred to *Nisusia*.)

Nisusia WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 247-248. (Described essentially as below as a new genus.)

Nisusia WALCOTT, GRABAU and SHIMER, 1907, North American Index Fossils, vol. 1, p. 210. (Characterized.)

Nisusia WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 4, Pl. XI, and pp. 142 and 147. (Classification of genus.)

Form subquadrate to transversely semioval. Shell structure dense with a minutely granular groundmass with minute pores penetrating some of the lamellæ forming the shell. The pores vary greatly in number and arrangement. Surface with narrow, radiating ribs that support irregularly distributed spines on their crests.

Ventral valve elevated and usually much more convex than the dorsal, and in most species a mesial sinus appears on it. Area high, vertical or inclined backward; delthyrium large and partly closed with a convex deltidium; teeth strong and supported by dental plates that extend outward, also inward, forming on the inside a shallow spondylium. Dorsal valve moderately convex with only a trace of a median elevation; usually the surface is convex, but it may be slightly concave from the umbo to the margins; crura well developed, with the crural plates extended so as to form a shallow cruralium. No traces of a cardinal process have been observed in the dorsal valve.

Type.—*Orthisina festinata* Billings.

Observations.—A comparison of the area of the ventral valve of *Nisusia* with that of the same valve in *Billingsella* shows in each a convex deltidium partly covering a large triangular delthyrium. In *Billingsella* the upper extremity of the deltidium is perforate and it is probably so in *Nisusia*, but on this point there is an uncertainty, as no specimen has been found clearly showing the pedicle opening. It may be that the deltidium of *Nisusia* was perforate in the younger stages of growth and subsequently filled by shell growth. The strong vascular sinuses of the ventral valve of *Billingsella* are absent in *Nisusia*, as well as the tripartite division of the umbonal cavity. The interiors of the dorsal valves of the two genera show marked differences. The cardinal process is well developed in *Billingsella* but not in *Nisusia*. There is a small, shallow cruralium in *Nisusia* but none in *Billingsella*. The dorsal valve of *Nisusia* has a clearly developed cruralium, but not any trace of a cardinal process. The ventral valve of *Billingsella* shows a tendency to form a spondylium resting on the interior of the valve, a character unknown in *Nisusia*.

The general form of *Nisusia* is not unlike that of *Billingsella* except that its ventral valve has a more erect beak and cardinal area. These comparisons include such species of *Billingsella* as *B. coloradoensis*, *B. plicatella*, and *B. exporrecta*, but not *B. dice* (Pl. CI, figs. 8, 8a-c). Of *Nisusia*, they include *N. festinata* and some of the subgenus *Jamesella*, such as *N. (J.) perpasta*, *erecta*, and *amii*.

Billingsella and *Nisusia* both occur in Lower Cambrian strata, but *Billingsella* has its greatest development in the Middle Cambrian and *Nisusia* in the Lower Cambrian. It is not

^a The synonymy for this genus does not give a complete record of the various genera under which the species now included in *Nisusia* were formerly placed; it gives only those references in which the genus is discussed or described. To complete the record the following mere generic references are listed:

Orthisina de Verneuil and Barrande [1860, p. 533].

Orthisina Billings [1861b, p. 10; 1861c, p. 949; 1862b, p. 105; 1862e, p. 221; 1863, p. 284].

Orthisina Mallada [1875, p. 32].

Orthisina Walcott [1886b, pp. 120 and 121; 1889c, p. 442; 1891a, p. 613].

Orthisina Tate [1892, p. 185].

Billingsella Schuchert [1897, p. 158].

Orthisina Matthew [1902c, p. 109].

probable that either genus is directly descendant from the other, but I think that both came from an ancestor that lived in early Lower Cambrian time and that *Billingsella* is further advanced in its development than *Nisusia*.

NISUSIA ALBERTA (Walcott).

Orthisina alberta Walcott, MATTHEW, 1902, Trans. Roy. Soc. Canada, 2d ser., vol. 8, sec. 4, No. 3, p. 109. (Original description, Walcott, 1889c, p. 442, copied.)

Nisusia alberta WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 248-249. (Described and discussed essentially as below.)

Nisusia alberta WALCOTT, 1908, Canadian Alpine Jour., vol. 1, No. 2, p. 245, Pl. I, figs. 4 and 4a. (No text reference. Figs. 4 and 4a are copied in this monograph, Pl. C, figs. 3c and 3d, respectively.)

Shell transversely suboval, front broadly rounded; the straight hinge line is shorter than the full width of the valves. Surface of shell with numerous radiating ribs that increase by interpolation; on a shell 19 mm. in width there are four ribs near the front margin in a distance of 3 mm.; the ribs are rather narrow and sharp crested, the interspaces being wider than the ribs. A cast of the outer surface of a shell in siliceous shales shows numerous strong spines irregularly distributed on the ribs very much as in *N. festinata* (Pl. C, fig. 3c).

Ventral valve elevated at the umbo and apex in some shells, convex and rounded over toward the area in others; area varying in height in different shells, usually elevated and overhanging the hinge line; it is divided by a strong delthyrium that is covered by a convex deltidium of varying length, arched at its front margin and divided by longitudinal lines into three parts.

Dorsal valve gently convex; area low, and a little inclined over the hinge line; delthyrium broad with a narrow chilidium. Casts of the interior show a broad, well-defined pseudocruralium and just in advance of it the adductor muscle scars.

Observations.—This species recalls at once *Nisusia festinata* by its elevated ventral valve and spinose surface; it differs from it by its transversely suboval outline, large umbonal muscle cavity (pseudocruralium) in the dorsal valve and sharp crested ribs. *Nisusia (Jamesella) perpasta* has the general form and surface characters of this species. A marked difference is caused by *N. alberta* occurring in a siliceous shaly matrix and *N. (Jamesella) perpasta* as casts in a quartzitic sandstone, and the strong surface spines of *N. alberta* are sparingly represented on the latter. A shell that appears to be identical with this species occurs at about 1,600 feet above the base of the Middle Cambrian terrane in Utah.

The specific name is derived from Alberta, Canada.

FORMATION AND LOCALITY.—**Middle Cambrian:** (14s) About 2,300 feet (701 m.) above the Lower Cambrian and 2,700 feet (823 m.) below the Upper Cambrian in the *Ogygopsis* zone of the Stephen formation [Walcott, 1908f, p. 210], at the "fossil bed," on the northwest slope of Mount Stephen; and (35k) Burgess shale member of the Stephen formation on the west slope of the ridge between Mount Field and Wapta Peak, 1 mile (1.6 km.) northeast of Burgess Pass; both above Field on the Canadian Pacific Railway, British Columbia, Canada.

Specimens that probably belong with *Nisusia alberta* occur at the following locality, together with other specimens that are somewhat doubtfully referred to the species:

Middle Cambrian: (54q) A drift block supposed to have come from a horizon 1,700 feet (518.2 m.) above the Brigham quartzite [Walcott, 1908a, p. 8], found near the mouth of Wasatch Canyon, east of Lakeview ranch, 5 miles (8 km.) north of Brigham, Boxelder County, Utah.

Specimens that appear to represent a variety of *Nisusia alberta* occur at the following localities:

Middle Cambrian: (57c and 57k) About 2,500 feet (762 m.) above the Lower Cambrian and 2,475 feet (754 m.) below the Upper Cambrian in the limestone forming 1 of the Stephen formation [Walcott, 1908f, p. 209]; and (58z) about 1,875 feet (572 m.) above the Lower Cambrian and 3,100 feet (945 m.) below the Upper Cambrian in the lime-

stone forming 2b of the Stephen formation [Walcott, 1908f, p. 211]; both on Mount Bosworth, north of the Canadian Pacific Railway between Hector and Stephen, on the Continental Divide between British Columbia and Alberta, Canada.

(57j) About 2,000 feet (609.6 m.) above the Lower Cambrian in the limestone forming 2 of the Stephen formation [Walcott, 1908c, p. 237 (6)], just east of the "fossil bed," on the northwest slope of Mount Stephen, above Field on the Canadian Pacific Railway, British Columbia, Canada.

Lower Cambrian: (58k) Just below the Middle Cambrian in the limestone forming 1 of the Mount Whyte formation [Walcott, 1908c, p. 240 (9)], just above the tunnel; and (58p) drift block of limestone believed to have come from the limestone forming 1 of the Mount Whyte formation [Walcott, 1908c, p. 240 (9)], found near the Canadian Pacific Railway track just west of the tunnel; both 3 miles (4.8 km.) east of Field, British Columbia, Canada.

NISUSIA COMPTA (Tate).

Plate XCVII, figure 14.

Orthisina compta TATE, 1892, Trans. Roy. Soc. South Australia, vol. 15, p. 185, Pl. II, figs. 6 and 6a. (Described as a new species. The specimen represented by figs. 6 and 6a is redrawn in this monograph, Pl. XCVII, fig. 14.)

Form transversely subquadrilateral with the hinge line a little shorter than the greatest width of the shell. Surface of the shell marked by strong, concentric ridges of growth that cause undulations of variable extent, also fine radiating, rounded, depressed ribs that are a little wider than the interstitial furrows. The outer surface is exfoliated, but the interior lamellæ of the shell show small, irregularly distributed nodes on the ribs that are considered to be the bases of spines similar to those on the surface of *Nisusia festinata* (Billings) (Pl. C, fig. 1) and *N. alberta* (Walcott) (Pl. C, fig. 3c).

The ventral valve is moderately convex with a low median fold. Area of medium width and projecting slightly backward; it is divided midway by a rather broad, triangular delthyrium that is nearly covered by a convex deltidium; the area and delthyrium are marked by fine transverse lines of growth.

Length of valve from beak to incurve of median fold, 6 mm.; greatest width, 9 mm.; length of hinge line, 7 mm.

Observations.—This species is represented in the collection before me by a single specimen. This appears to be a ventral valve, but, unlike the ventral valve of *N. festinata* (Pl. C, figs. 1, 1a-d), which has a median sinus, it has a median fold. The area and convex deltidium are like those of the ventral valve of *N. festinata*. The fine ribs and quadrate form distinguish this species from other species of the genus.

FORMATION AND LOCALITY.—Middle? Cambrian: (315 [Tate, 1892, p. 185]) Limestone at Curramulka, Yorke Peninsula, South Australia.

Nisusia festinata (Billings), WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 249-251. (Described and discussed essentially as on p. 728.)

Nisusia festinata (Billings), GRABAU and SHIMER, 1907, North American Index Fossils, vol. 1, p. 211, fig. 249, p. 210. (Described. Fig. 249 is copied from Walcott, 1886b, Pl. VII, figs. 7, 7a-b.)

General form subquadrate to transversely semioval, with the cardinal extremities subacute to obtusely angular. Hinge line straight, usually equal to or greater in length than the width of the body of the shell. Shell substance dense, granular, with minute pores arranged in scattered radiating lines; none of the pores appear to pass through more than one lamella of the shell.

Surface with narrow, rounded, radiating ribs, that increase by both bifurcation and interpolation; the ribs are roughened by concentric lines and ridges of growth that arch about the base of strong, acute spines; the spines are located on the ribs, usually just back of a ridge of growth; they are in more or less irregular, concentric rows toward the front of the shell, but on the central portions they may be scattered without any system of arrangement; each spine is larger at the base, tapering rapidly, and curving gradually backward at about one-half its length.

The ventral valve is more or less elevated at the umbo and apex; in some examples it is subpyramidal (Pl. C, fig. 1e), where the height is to the length as 3 to 6, and width 9 mm.; in other shells the proportion is 4 to 11, and width 17 mm.; the slopes from the apex to the margins are nearly straight or slightly convex; the form of the umbo and apex varies from a broad, rounded umbo terminating in a minute beak curving over the area, to an erect, vertical, more or less rounded apex, with a broad base rising abruptly from the elevated umbo; a shallow, rounded, median sinus occurs on most shells, but it is sometimes absent. Area high, and crossed by transverse lines of growth; it is usually inclined over the hinge line, but it may be vertical or inclined forward (fig. 1e); it is divided by a strong delthyrium, which is covered by a convex deltidium that the author of the species, Billings, describes [1861c, p. 10] as perforate at the apex.^a I have not been able to verify this in a large collection of material from various localities; casts of the interior of the extended beak indicate but do not prove that there was a perforation; the front edge of the deltidium is arched so as to leave a space of variable height between it and the plane of the hinge line; in three examples the area is divided into three parts by longitudinal lines (Pl. C, fig. 1e''), two of the lines bound the delthyrium, and one on each side corresponds in position to the "flexure" lines in *Obolus* and *Hipparionyx*. A cast of the interior of a low ventral valve (Pl. C, fig. 1f') shows a broad delthyrium, strong teeth, and supporting dental plates which are produced on the inside so as to form a short, elevated base (pseudospondylium), and on the outside the plates are continued partly about the space occupied by the points of attachment of the diductor muscles.

The dorsal valve is moderately convex at the umbo, sloping gently from there to the margins; usually the slope is convex, but in one example it is slightly concave; area narrow and vertical or slightly inclined over the hinge line; casts of the interior show the crura, points of attachment of posterior adductor scars (e, Pl. C, fig. 1g; see fig. 3a), area of attachment of diductor scars (d', Pl. C, figs. 1g, 1i). Vascular and ovarian markings unknown.

Observations.—This shell has a wide geographic distribution. I have collected it at the type locality in the township of Georgia, Vermont; at Bic on the lower St. Lawrence River; and near York, Pennsylvania. The matrix at Bic is a finely granular, slightly arenaceous limestone in which the outer form of the shell is well preserved, but the spines are rarely seen. At Swanton and Georgia, Vermont, the shell occurs in siliceous limestone and arenaceous shale, and a cast of the outer surface shows the spines; the material from the finely arenaceous limestone at the Emigsville localities, discovered by A. Wanner, of York, Pennsylvania, is the best preserved and affords excellent casts of the interior and exterior of the valves. In all of the localities the variation in the form and elevation of the ventral valve occurs; specimens of the ventral valve from Bic, Canada, show a shorter deltidium than is usually present. A number of exfoliated shells occur in the collection from the dark-gray compact limestones of eastern New York and are doubtfully referred to this species.

^a Through the courtesy of Dr. J. F. Whiteaves, of the Geological Survey of Canada, I had the opportunity of examining the types of "*Orthisina festinata*." None of them preserve the apex of the deltidium, so it is impossible to determine upon what Billings based his statement that the deltidium was perforate.

Nisusia festinata is a strongly marked species that appears to have but one near representative in form, *N. (Jamesella) perpasta*. It differs from the latter species in the absence of spines and in the form of the ventral valve.

FORMATION AND LOCALITY.—Lower Cambrian: (392a) Limestones at L'Anse au Loup, on the north shore of the Straits of Belleisle, Labrador.

(20) Limestone boulders in conglomerate, on shore at east entrance to harbor at Bic, Rimouski County, Quebec, Canada.

(25a) Limestone on the Hall (Donaldson's) farm, 2 miles (3.2 km.) east of Swanton; (319e [Billings, 1861b, p. 10]) limestone 2 miles (3.2 km.) east of Swanton; (25) sandstone just above Parker's quarry, near Georgia; (319m) shales of No. 6 of the section at Parker's quarry [Walcott, 1891b, p. 278], near Georgia; (26) sandstone northeast of the Corman farm buildings, east of Highgate Springs; and (392p) shale on the Jewell farm; all in Franklin County, Vermont.

(319w) Limestone 1.25 miles (2 km.) north of Rutland, Rutland County, Vermont.

(38a) Limestone 2 miles (3.2 km.) south of North Granville, on the road which turns south from the road running between that village and Truthville, 4 miles (6.4 km.) west-northwest of Granville, Fort Anu quadrangle (U. S. Geol. Survey); and (36) limestone 1 mile (1.6 km.) south of Shushan and 3.5 miles (5.6 km.) north-northeast of Cambridge, Cambridge quadrangle (U. S. Geol. Survey); both in Washington County, New York.

(49) Sandstone on Codorus Creek, 0.125 mile (0.2 km.) below Meyer's mill, near Emigsville; (49a) sandstone on the Liverpool road, south of the schoolhouse, 3 miles (4.8 km.) northwest of York; (346e) shale near York; and (49w) limestone in railroad cut 0.25 mile (0.4 km.) south of Emigsville; all in York County, Pennsylvania.

(35f) About 300 feet (91 m.) below the Middle Cambrian in the limestone forming 6 of the Mount Whyte formation [Walcott, 1908c, p. 242 (11)] just above the tunnel on the north shoulder of Mount Stephen, about 3 miles (4.8 km.) east of Field, British Columbia, Canada.

(35h) About 375 feet (114 m.) below the Middle Cambrian in the shales of No. 4 of the Mount Whyte formation [Walcott, 1908f, p. 214], on Mount Bosworth, north of the Canadian Pacific Railway between Hector and Stephen, on the Continental Divide between British Columbia and Alberta, Canada.

NISUSIA FESTINATA TRANSVERSA (Walcott).

Plate C, figures 4, 4a-b.

Orthisina? transversa WALCOTT, 1886, Bull. U. S. Geol. Survey No. 30, p. 121, Pl. VII, figs. 5 and 5a. (Described as below as a new species. The specimens represented by figs. 5 and 5a are redrawn in this monograph, Pl. C, figs. 4 and 4a, respectively.)

Orthisina? transversa WALCOTT, 1891, Tenth Ann. Rept. U. S. Geol. Survey, p. 613, Pl. LXXII, figs. 9 and 9a. (No text reference. Figs. 9 and 9a are copied from figs. 5 and 5a, respectively, of the preceding reference.)

Nisusia festinata transversa WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 251. (Original description copied as below and species placed as variety of *Nisusid festinata*.)

Shell small, transversely subquadrangular in outline, front broadly rounded, angle formed by the union of the cardinal slopes of the ventral valve 155° to 165° , hinge line straight and as long as the width of the shell. Area of the ventral valve of moderate height, bent back from the hinge line, divided by a triangular foramen that is higher than wide and covered by a convex deltidium; the area of the dorsal valve is bent back at more than right angles to the hinge line; foramen higher than wide, covered by a deltidium.

Surface marked by numerous radiating, fine, even costæ, eight in a distance of 3 mm. on the frontal margin of the ventral valve; a few concentric lines of growth cross the radiating costæ, but not so as to give them a nodose character.

Interior characters unknown. The fine radiating striæ and transverse form distinguish this from other described species known to me.

FORMATION AND LOCALITY.—Lower Cambrian: (25) Sandstone just above Parker's quarry, near Georgia; (319m) shales of No. 6 of the section at Parker's quarry [Walcott, 1891b, p. 278], near Georgia; and (25a) limestone on the Hall (Donaldson's) farm, 2 miles (3.2 km.) east of Swanton; both in Franklin County, Vermont.

NISUSIA RARA Walcott.

Text figure 60, page 730.

Nisusia rara WALCOTT (in part), 1908, Smithsonian Misc. Coll., vol. 53, No. 3, p. 97, Pl. IX, fig. 13a (not fig. 13, which represents a specimen of *Eoorthis thylene*). (Characterized and discussed as below as a new species. Fig. 13a is copied in this monograph as fig. 60, p. 730.)

The ventral valve of this species has the same general form as that of *Nisusia festinata* (Billings) (Pl. C, figs. 1d and 1e) except that it has a very strong and deep median sinus and

is more transverse; the delthyrium is also larger. *Nisusia rara* occurs at the same stratigraphic horizon as *Nisusia alberta* (Walcott), but it differs from the latter in having a larger delthyrium and a strong and deep median sinus.

The surface of *N. rara* is marked by rounded radiating ribs that increase by interpolation and bifurcation; small nodes on some of the ribs indicate the presence of spines on the outer surface. A portion of a convex deltidium is shown that has the outer portion broken away. The type specimen has a length of 8 mm.; width, 16 mm.

FORMATION AND LOCALITY.—Middle Cambrian: (55c) Spence shale member of the Ute limestone [Walcott, 1908a, p. 8], about 50 feet (15.2 m.) above the Brigham quartzite and 2,755 feet (839.7 m.) below the Upper Cambrian, in a ravine running up into Danish Flat from Mill Canyon, about 6 miles (9.6 km.) west-southwest of Liberty and 15 miles (24.2 km.) west of Montpelier, Bear Lake County, Idaho.

FIGURE 60.—*Nisusia rara* Walcott. Cast of the interior of a dorsal valve (U. S. Nat. Mus. Cat. No. 52295a, labeled 52295b [Walcott, 1908d, p. 123] by error).^a The specimen represented is from Locality 55c, Middle Cambrian Spence shale, near Liberty, Idaho. The figure is copied from Walcott [1908d, Pl. IX, fig. 13a].

NISUSIA? VATICINA (de Verneuil and Barrande).

Plate XCVII, figures 3, 3a-b.

Orthisina vaticina DE VERNEUIL and BARRANDE [not SALTER MS.], 1860, Bull. Soc. géol. France, 2d ser., vol. 17, pp. 533-535, Pl. VIII, figs. 8, 8a-d. (Described and discussed in French as a new species; see below for translation. Figs. 8, 8b-c are copied in this monograph, Pl. XCVII, figs. 3, 3a-b, respectively.)

Orthisina vaticina de Verneuil and Barrande, MALLADA, 1875, Bol. Com. Mapa Geológico España, tome 2, p. 32. (Mentioned.)

The original description by de Verneuil and Barrande follows:

Shell subquadrangular, slightly emarginate below the lateral extremities. Length equal to three-fourths of the breadth. Hinge ridge somewhat shorter than the greatest width of the shell. Ventral valve twice as thick as the dorsal, area double in height. Triangular opening on each of the valves, covered in part by a deltidium. At the point of the beak there is a very fine opening, hardly visible, which is obliterated in certain specimens. The valves are regularly bulged and have no marked sinus, so that their edge is straight. The surface is ornamented with fine, dichotomous, spiny striae; these spines, or tubes, which are 1 or 2 mm. long on the ventral valve, are hardly seen on the other valve. At 10 mm. from the beak, where the striae subdivide by dichotomy, six of them are counted in a space of 5 mm.

Dimensions: Length, 18 mm.; breadth, 24 mm.; thickness, 8 mm.

Relations and differences: This species belongs to the *Orthis* group, united by one of us under the name of *Recto striatae*^b and which Davidson includes in the genus *Orthisina* of d'Orbigny.^c The two characteristics of this group consist in the direction of the striae, which, starting from the beak, never curve backward to reach the hinge crest, and in the presence of a deltidium which covers the triangular cleft of the area. The hole with which this deltidium is sometimes pierced, a characteristic on which d'Orbigny established the genus *Orthisina*, is of altogether secondary importance, for it appears to be only temporary. We have demonstrated that in certain *Leptaena*, which have an opening analogous to that of the species under discussion, that characteristic produces no significant change in the internal apparatus.^d

In having its striae provided with tubes or spines this species is distinguished from all others, except *O. striatula*, with which it is impossible, on other accounts, to confound it. It may be compared either to *O. romingeri* Barrande, from the primordial zone of Bohemia, which is distinguished by a rather pronounced sinus on the small valve, a more prominent beak and smooth striae; or with *O. inflexa* Pander, from the lower Silurian strata of St. Petersburg, which is thicker, as observed especially in the dorsal valve, which in this respect is almost equal to the opposite valve. Moreover the striae of the Russian species are never spinous.

Mr. Salter, whose kindness is never appealed to in vain, thought he recognized in our specimens a species found recently in the *Lingula* beds, to which, in the collection of the museum of practical geology at London, he gave the name *O. vaticina*, under which we publish it.

Observations.—In appearance this shell is closely related to Lower Ordovician species of *Clitambonites* that have a fimbriated surface. If, as the authors state, many of the shells are imperforate, then it is probable that the species is closely related to and belongs with *Nisusia*, although the illustration of the spines indicates that they were of a different character from those of *Nisusia festinata* (Billings). In the presence of the statement that the shells are associated with the Primordial fossils (*Paradoxides*, etc.) and the absence of an opportunity to

^a See the note accompanying the first reference in the synonymy of *Eoorthis thylene*, p. 789, and the note following text figures 70A-C, p. 789.

^b Murchison, de Verneuil, et de Keyserling, Géologie de la Russie d'Europe et de l'Oural, vol. 2, 1845, p. 179. Bull. Soc. géol. France, 2d ser., vol. 2, 1845, p. 481.

^d De Verneuil, Bull. Soc. géol. France, 2d ser., vol. 5, 1848, p. 348.

study the actual specimens, I think it best to refer the species to *Nisusia*. "*Orthis vaticina*" was a manuscript name given by Salter to shells subsequently referred to "*Orthis lenticularis*" by Davidson [1869, p. 231].

FORMATION AND LOCALITY.—Middle Cambrian: (350 [de Verneuil and Barrande, 1860, p. 538]) Red limestone of the *Paradoxides* zone, near Adrados, north of Sabero and Boñar, Cantabrian Mountains, Province of Leon, northwestern Spain.

JAMESELLA Walcott,^a subgenus of **NISUSIA**.

Nisusia (*Jamesella*) WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 252. (Characterized as below as a new subgenus.)

Nisusia (*Jamesella*) WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 4, Pl. XI, and pp. 142 and 147. (Classification of genus.)

There are several species of Lower Cambrian brachiopods that differ from *Nisusia festinata* in the absence of the strong spines on the radiating ribs. This character is so marked that I separate the species without it as a subgeneric group.

Type.—*Orthis perpasta* Pompeckj.

The subgeneric name is in memory of Dr. Joseph F. James, a paleontologist who assisted me in the preparation of material for the study of the *Olenellus* fauna.

NISUSIA (**JAMESELLA**) **AMII** Walcott.

Plate CI, figures 6, 6a-b.

Nisusia (*Jamesella*) *amii* WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 252. (Described and discussed as below as a new species.)

Ventral valve convex, elevated at the umbo, with the beak slightly incurved; area high, vertical, slightly incurved; delthyrium triangular, higher than its greatest width and covered by a convex deltidium, which is imperforate. Surface of shell marked by numerous fine, rounded, equidistinct ribs that increase by interpolation; about 8 ribs in a distance of 2 mm. at frontal margin. Size: Length, 8 mm.; width, 10 mm.; elevation at umbo, 4 mm.

The front margin of the deltidium is broken so that it is impossible to state whether it was arched as is the deltidium of *Nisusia festinata* (Billings). There is no trace of a foraminal aperture in the deltidium. The fine, regular ribs and high area serve to distinguish this from other species of the genus. Dorsal valve unknown.

The specific name was given in honor of Dr. H. M. Ami.

FORMATION AND LOCALITY.—Lower Cambrian: (56a) A limestone boulder in the Sillery conglomerate, on the south shore of St. Lawrence River 4 miles (6.4 km.) below Quebec, Canada.

NISUSIA (**JAMESELLA**) **ARGENTA** Walcott.

Plate CI, figures 9, 9a-b.

Nisusia (*Jamesella*) *argenta* WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 252. (Described and discussed somewhat as below as a new species.)

The outline of the ventral valve is subrectangular, with the hinge line a little shorter than the greatest width. Strongly convex with a keel-like median elevation extending from the incurved beak over the elevated umbo to the front margin, with gradually increasing width. Area low, with the minute beak curving down to and possibly slightly over it.

Dorsal valve depressed, convex, with a rather strong median fold (Pl. CI, fig. 9b); area unknown.

^a The synonymy for this subgenus does not give a complete record of the various genera under which the species now included in *Jamesella* were formerly placed; it gives only those references in which the genus is discussed or described. To complete the record the following mere generic references are listed:

Orthis Feistmantel.
Orthis Jahn.
Orthis Katzer.
Orthis Krejci.
Orthis Kusta.

Orthis Novak.
Orthis Wentzel.
Orthisina de Verneuil and Barrande [1860, p. 535].
Orthis Pompeckj [1896b, p. 514, 515, and 516].
Protorthis Walcott [1905a, pp. 283 and 285].

Surface marked by fine, concentric striae of growth and about five sharp, elevated, radiating ribs on each side of the two ribs on the median ridge of the ventral valve; the ribs of the dorsal valve are more regular in spacing and size.

Observations.—This shell has such strong characters that I unhesitatingly give it a specific name. The only form known to me that resembles it is *N. (J.) kuthani* (Pompeckj) (Pl. CI, figs. 4, 4a-b) from Bohemia.

FORMATION AND LOCALITY.—**Lower Cambrian:** (1m and 1p)^a Limestones of No. 2 of the Silver Peak group, Barrel Spring section [Walcott, 1908f, p. 189], about 2.5 miles (4 km.) south of Barrel Spring and 0.5 mile (0.8 km.) east of the road, in the extreme southeast corner of the Silver Peak quadrangle (U. S. Geol. Survey), Esmeralda County, Nevada.

NISUSIA (JAMESELLA) ERECTA Walcott.

Plate CI, figures 5, 5a-b.

Nisusia (Jamesella) erecta WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 253. (Described essentially as below as a new species.)

General form transversely semioval; hinge line a little shorter than the greatest width; Valves subequally convex. Surface marked by strong, broad, sharply rounded ribs, three at the frontal margin in a distance of 2 mm.; the ribs appear to be simple and unbifurcated from the umbo to the margin, but owing to the small size of the shell this statement may be modified by discovery of other specimens. Width, 9 mm.; length, 7 mm. from beak to front of ventral valve.

Ventral valve convex; elevated at the umbo, beak marginal. Area high, very slightly inclined backward; delthyrium large, triangular, length and width equal; deltidium convex, imperforate, and nearly covering the delthyrium. Dorsal valve regularly convex, most elevated at the umbo and curving over to the rather low area.

This species is distinguished by its strong, regular ribs and regular convexity of the dorsal valve.

FORMATION AND LOCALITY.—**Middle Cambrian:** (313g) Limestone at the south end of the Timpahute Range, Groome district, near the line between Nye and Lincoln counties, Nevada.

NISUSIA ? (JAMESELLA ?) KANABENSIS Walcott.

Nisusia ? (Jamesella ?) kanabensis WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 3, pp. 97-98. (Described and discussed as below as a new species.)

This species is represented by a single broken interior cast of a small ventral valve that has a length of 3.5 mm.; width, about 5 mm. The cast is convex, with the base of a prominent extension that filled the interior of the beak. The surface is finely papillose, which proves that the interior surface was finely punctate. The casts of the ribs show them to have been rather sharply rounded and to have increased by bifurcation and interpolation; the absence of all traces of casts of spine bases on the ribs leads me to refer the species to the subgenus *Jamesella*. Area shown only by a narrow rim on one side. The delthyrium was probably quite broad.

The reference of this shell to *Nisusia* is based on the evidence of the presence of a prolonged beak and the character of the ribs. The genus is doubtful, but I do not know of any other to which a tentative reference could be made.

The specific name is derived from Kanab Canyon, the type locality.

FORMATION AND LOCALITY.—**Upper Cambrian:** (75) Thin-bedded limestones just below the base of the Ordovician, in the Tonto group, near the water's edge at the mouth of Kanab Canyon, Grand Canyon of the Colorado, Arizona.

NISUSIA (JAMESELLA) KUTHANI (Pompeckj).

Plate CI, figures 4, 4a-b.

Orthis kuthani POMPECKJ, 1896, Jahrb. K.-k. geol. Reichsanstalt, Bd. 45, pp. 514-515, Pl. XV, figs. 8-13. (Described and discussed in German as a new species; see p. 733 for translation.)

Orthis romingeri of the following authors: KREJCI, NOVAK, K. FEISTMANTEL, KUSTA, KATZER, WENTZEL, and JAHN.

^a 1p is the type locality.

Nisusia (Jamesella) kuthani Pompeckj, WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 253-254. (Original description, Pompeckj, 1896b, p. 514, copied, and species discussed as below.)

The original description by Pompeckj follows:

Outline subrectangular, hinge edge straight with angles protracted but a short distance; length to breadth as 3:4, often less.

Ventral valve highly arched. Apex drawn forward, but not curved toward the dorsal valve at all, or in rare cases but slightly. Area high, steep, with sharp areal edges and high, triangular foramen. Owing to the state of preservation, the details of the interior of the valves can not be well observed.

Dorsal valve flatter, with rather decided arching on side edge and frontal edge, with sinus always distinct, which corresponds to a faint swelling at the frontal edge of the ventral valve. The area is very low with a small triangular foramen. Crural processes narrow, considerably divergent.

The surface is ornamented with narrow sharp ribs, increasing by interpolation. The ribs are divided by interspaces which are considerably broader than the ribs. In the interspaces there is frequently seen a lower, threadlike rib. The number of ribs is 30 to 36. The ribs are mostly very distinct on the internal casts also. Sometimes internal casts are found which show remarkably few ribs, and which in this respect and also in their greater breadth approach *Orthis perpasta* var. *macra*.

The present species has thus far been called, after Kusta's example, *Orthis romingeri*, but it differs from that species (a) in the ventral valve, its apex never being so strongly curved as in *Orthis romingeri*, and in most cases not curved at all; (b) in the dorsal valve, which in the present species is more strongly arched with a more decided sinus; (c) in the sculpture, inasmuch as the ribs are narrower, sharper, fewer in number, and separated by wider interspaces than in *Orthis romingeri* Barrande.

Observations.—In the material of this species sent me by Doctor Pompeckj there is one cast of a ventral valve that shows that a convex deltidium covered about two-thirds of the delthyrium; its front margin was arched so as to leave considerable space open between it and the plane of the hinge line.

There is a decided mesial sinus in most specimens of the dorsal valve, but in some it is flattened so as scarcely to break the uniform low convexity of the valve; the strength of the mesial elevation of the ventral valve also varies from a marked ridge to a flattened median space.

The species appears to be quite distinct from any described Cambrian form.

The specific name was given in honor of Mr. Wilhelm Kuthan, of Tejšovik, Bohemia, Austria-Hungary.

FORMATION AND LOCALITY.—Lower Cambrian: Conglomeratic sandstones and graywacke inclusions in the lower conglomerate zone of the Kamenná hůrka at the following localities [Pompeckj, 1896b, p. 514]: (345i)^a near Tejšovik, and (345j) at Gross Lohovic, southwest of Skrej; both in Bohemia, Austria-Hungary.

(345k)^a Sandstones at Slapnický mlýn, near Skrej, Bohemia, Austria-Hungary.

NISUSIA (JAMESELLA) LOWI Walcott.

Text figures 61A-D, page 734.

Nisusia (Jamesella) lowi WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 3, p. 98, Pl. IX, fig. 14. (Characterized and discussed essentially as below as a new species. Fig. 14 is copied in this monograph as fig. 61A.)

The description of the form, outline, convexity, and cardinal area of the ventral valve of *Nisusia festinata* (Billings) (Pl. C, figs. 1, 1a-e) is so applicable to this species that I will refer the student to it for the description of those features. The surface of *Nisusia (Jamesella) lowi* differs from that of *N. festinata* in having more and finer radiating ribs, clearly defined, rounded, concentric striae and lines of growth, and in the absence of all traces of the surface spines so characteristic of *N. festinata*. The latter is also a larger species. *Nisusia (Jamesella) lowi* averages 10 to 12 mm. across the hinge line and rarely over 8 mm. in the length of the ventral valve of the large shells of the species.

There is a close relationship between *Nisusia alberta* (Walcott) (Pl. C, figs. 3, 3a-d) and *N. (J.) lowi* in form and size. *N. alberta* has a spinose surface, and the beds in which the two species occur are separated by 1,700 feet of limestone.

^a Localities 345i and 345k are represented in the collections of the United States National Museum.

The specific name is given in honor of Hon. A. P. Low, deputy head and director of the Geological Survey of Canada.

Nisusia (Jamesella) lowi occurs at horizons 186 to 294 feet (56.7 to 89.6 m.) above the horizon of *Nisusia festinata* (Billings) in the Mount Stephen section.

FORMATION AND LOCALITY.—Lower Cambrian: (58k) Just below the Middle Cambrian in limestones forming 1 of the Mount Whyte formation [Walcott, 1908c, p. 240 (9)], just above the tunnel; (58p) drift block of limestone believed to have come from the limestone forming 1 of the Mount Whyte formation [Walcott, 1908c, p. 240 (9)], found near the

FIGURE 61.—*Nisusia (Jamesella) lowi* Walcott.—A, A', A'', Top, side, and enlarged view (X9) of exterior surface of a partly exfoliated ventral valve, the type specimen, in limestone (U. S. Nat. Mus. Cat. No. 53677a). B, B', B'', Top, side, and back views of cast of the interior of a ventral valve, in limestone (U. S. Nat. Mus. Cat. No. 53677b). C, View of the cast of the interior of a small dorsal valve, in limestone (U. S. Nat. Mus. Cat. No. 53677c). D, A compressed dorsal valve in siliceous shale (U. S. Nat. Mus. Cat. No. 57072a).

The specimens represented by figures 61A, 61B, and 61C are from Locality 58k, and that represented by 61D is from Locality 57m, both in the Lower Cambrian on Mount Stephen, British Columbia. Figure 61A is copied from Walcott [1908d, Pl. VIII, fig. 14].

Canadian Pacific Railway just west of the tunnel; and (57m) about 50 feet (15.2 m.) below the Middle Cambrian in a siliceous shale correlated with 1b of the Mount Whyte formation on Mount Bosworth [Walcott, 1908f, p. 213], just above the tunnel; all on the north shoulder of Mount Stephen, 3 miles (4.8 km.) east of Field, British Columbia, Canada.

(57s) About 160 feet (49 m.) below the Middle Cambrian near the base of the gray oolitic limestone forming 1b of the Mount Whyte formation [Walcott, 1908f, p. 212], on Mount Bosworth, north of the Canadian Pacific Railway between Hector and Stephen, on the Continental Divide between British Columbia and Alberta, Canada.

NISUSIA (JAMESELLA) NAUTES (Walcott).

Plate XCIII, figures 6, 6a-b.

Protorthis nautes WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 283-284. (Characterized and discussed somewhat as below as a new species.)

This species has the same type of punctate interior surface as *N. (J.) spencei*, and casts of the exterior are marked by minute, closely set papillæ that are casts of the punctæ in the shell. Traces of the shell show the same type of papillæ and it is highly probable that the shell was punctate. The exterior form is like that of *Nisusia alberta*, but in the surface ribs it differs from the latter and other described species of the genus.

A ventral valve has a length of 5 mm.; width, 8 mm. A dorsal valve, length, 7 mm.; width, 10 mm. There is considerable variation in the relative proportions between length and width.

FORMATION AND LOCALITY.—Middle Cambrian: (55e and 163)^a Spence shale member of the Ute limestone [Walcott, 1908a, p. 8], about 50 feet (15.2 m.) above the Brigham quartzite, and 2,755 feet (839.7 m.) below the Upper Cambrian, in a ravine running up into Danish Flat from Mill Canyon, about 6 miles (9.6 km.) west-southwest of Liberty and 15 miles (24.2 km.) west of Montpelier, Bear Lake County, Idaho.

^a 163 is the type locality.

Specimens that are somewhat doubtfully referred to *Nisusia* (*Jamesella*) *nautes* occur at the following localities:

(15c) Limestone in the Marjum limestone, near Swasey Spring; and (11q) about 2,350 feet (716.3 m.) above the Lower Cambrian, and 2,050 feet (624.8 m.) below the Upper Cambrian in the limestone forming 1c of the Marjum limestone [Walcott, 1908f, p. 180] ridge east of Wheeler Amphitheater; both in the House Range [Walcott, 1908f, Pls. XIII and XV], Millard County, Utah.

(57f) About 2,200 feet (670.6 m.) above the Lower Cambrian, and 2,800 feet (853.4 m.) below the Upper Cambrian, in the limestone forming 1 of the Stephen formation [Walcott, 1908f, p. 209], about 0.5 mile (0.8 km.) east of the "fossil bed," on the northwest slope of Mount Stephen, above Field, on the Canadian Pacific Railway, British Columbia, Canada.

NISUSIA (*JAMESELLA*) PELLICO (de Verneuil and Barrande).

Plate XCVII, figures 2, 2a-b.

Orthisina pellico DE VERNEUIL and BARRANDE, 1860, Bull. Soc. géol. France, 2d ser., vol. 17, pp. 535-536, Pl. VIII, figs. 7, 7a-b. (Described and discussed in French as a new species; see below for translation. Figs. 7, 7a-b are copied in this monograph, Pl. XCVII, figs. 2, 2a-b, respectively.)

The original description by de Verneuil and Barrande follows:

Shell rather small, transverse, breadth greater than length by one-fourth, cut off squarely at the extremities. Hinge crest attains the greatest breadth of the shell. Ventral valve twice as deep as dorsal valve, provided with an area of twice the height, which rises perpendicularly and forms a right angle with the hinge crest. The opening is only partly covered with a deltidium, which descends from the tip of the beak. On the other valve the bare rudiments of a similar deltidium may be perceived.

Neither valve has a sinus, and their commissure presents no wavy contours.

The surface is ornamented with rather wide-spaced striæ. Three or four principal striæ are counted on the sides, and two or three intermediate finer ones. The median region is bounded by two pronounced striæ, between which two or three fainter ones are distinguished.

Dimensions: Breadth, 11 mm.; length, 8 mm.; thickness, 5 mm.

Relations and differences: In having its area partly covered with a deltidium this species comes within the genus *Orthisina*, as understood by Mr. Davidson, but it no longer shows the needle-shaped hole of the tip, on which d'Orbigny had established the genus. However, the analogy which it maintains with the preceding species does not admit of its being placed in any other genus, and shows how slight is the importance of the characteristic used by the author just named. The position of the area, with regard to the hinge, recalls *O. adscendens*, which is clearly distinguished from our species by the nature of its striæ.

From this last-named point of view *O. pellico* approaches the *Leptænæ* more than it does most of the other *Orthis* or *Orthisina* species.

Observations.—As far as the illustrations and description can determine, this species belongs with the nonspinose forms of *Nisusia* grouped under the subgenus *Jamesella*.

The authors of the species state [1860, p. 536] that this shell was found in the red limestone with their "*Orthis primordialis*."

FORMATION AND LOCALITY.—Middle Cambrian: (350 [de Verneuil and Barrande, 1860, p. 538]) Red limestone of the *Paradoxides* zone, near Adrados, north of Sabero and Boñar, Cantabrian Mountains, Province of Leon, northwestern Spain.

NISUSIA (*JAMESELLA*) PERPASTA (Pompeckj).

Plate CI, figures 1, 1a-h.

Orthis perpasta POMPECKJ, 1896, Jahrb. K.-k. geol. Reichsanstalt, Bd. 45, pp. 515-516, Pl. XV, figs. 15-18. (Described and discussed in German as a new species; see below for translation. Fig. 16d is copied in this monograph, Pl. CI, fig. 1g.)

Nisusia (*Jamesella*) *perpasta* POMPECKJ, WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 254-255. (Original description, Pompeckj, 1896, pp. 515-516, copied, and species discussed as essentially on p. 736.)

The original description by Pompeckj follows:

Outline subrectangular, with straight hinge line and slightly bent frontal margin; cardinal angles slightly drawn in; the length is little more than half the breadth, the greatest breadth being in the middle of the valves. Both valves are very strongly arched.

The ventral valve has a high, steep area, with a large triangular foramen, and the areal edges are rather sharp. The apex is not drawn forward beyond the hinge line. From the apex to the frontal edge there is a sinus which gradually increases to a considerable breadth. The dorsal valve, which is also strongly arched, has a very low and

indistinct area, with a low, broadly triangular foramen. On the frontal margin a strong, broad swelling of the edge of the valve corresponds to the sinus of the ventral valve.

Judging by some internal casts and impressions, the shell is ornamented with some 40 broad ribs, of which about half are inserted between the primary ribs at various distances from the apex. Concentric lines of growth cross the ribs. On the top of the shells, along some of these lines of growth (1 or 2) the sections of the shell are found to be imbricated; near the frontal edge such imbrication is present more frequently in very short intervals.

Orthis perpasta differs from *Orthis kuthani* in its greater breadth, in the almost uniform and much stronger arching of both valves, and also in the fact that in the former species the ventral valve bears a sinus, whereas in *Orthis kuthani* the sinus is on the dorsal valve.

Observations.—Doctor Pompeckj very kindly sent me several fragments of sandstone containing casts of the interior and exterior of the valves. The specimens illustrated by Pompeckj [1896b, Pl. XV] are smoother than most of those sent to me, but the description corresponds to the ribbed specimens and a few nearly smooth interior casts occur in association with the more strongly ribbed shells. The convexity of the ventral valve is quite variable, but is usually considerable. One of the marked characters of the dorsal valve is the large transverse space (pseudocruralium) inside the valve beneath the umbo. In one example it is crossed vertically by the main vascular sinuses. What may be a trace of a low, simple, rounded cardinal process is shown in one cast. The crura were strong, with small dental sockets beside them.

Nisusia (Jamesella) perpasta resembles *Nisusia alberta* (Walcott) in form and convexity, but it does not have a spinose surface.

FORMATION AND LOCALITY.^a—Lower Cambrian: Conglomeratic sandstones and graywacke inclusions in the lower conglomerate zone of the Kamenná hůrka at the following localities [Pompeckj, 1896b, p. 516]: (345i) near Tejřovik; and (345j) at Gross Lohovic, southwest of Skrej; both in Bohemia, Austria-Hungary.

(345k) Sandstones at Slapnický mlýn, near Skrej, Bohemia, Austria-Hungary.

NISUSIA (JAMESELLA) PERPASTA MACRA (Pompeckj).

Plate CI, figures 3, 3a.

Orthis perpasta macra POMPECKJ, 1896, Jahrb. K.-k. geol. Reichsanstalt, Bd. 45, p. 516, Pl. XV, fig. 14. (Characterized in German as a new variety; see below for translation. Fig. 14 is copied in this monograph, Pl. CI, fig. 3a.)

Nisusia (Jamesella) perpasta macra Pompeckj, WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 255. (Original characterization copied and variety discussed as below.)

The original description by Pompeckj follows:

Some internal casts and impressions of dorsal valves agree in outline perfectly with the dorsal valves of *Orthis perpasta*, but differ from the type form by much less arching and ribs farther apart.

Observations.—The gradual increase in the width of the interspaces between the ribs, from a very narrow space to several times the width of the rib, makes this variety of doubtful value.

FORMATION AND LOCALITY.—Lower Cambrian: Conglomeratic, quartzitic sandstones and graywacke inclusions in the zone of the Kamenná hůrka at the following localities [Pompeckj, 1896b, p. 516]: (345i) near Tejřovik; and (345j) at Gross Lohovic, southwest of Skrej; both in Bohemia, Austria-Hungary.

NISUSIA (JAMESELLA) PERPASTA SUBQUADRATA (Pompeckj).

Plate CI, figures 2, 2a-b.

Orthis perpasta subquadrata POMPECKJ, 1896, Jahrb. K.-k. geol. Reichsanstalt, Bd. 45, p. 516, Pl. XV, figs. 19 and 20. (Described and discussed in German as a new variety; see below for translation. Figs. 19a and 20a are copied in this monograph, Pl. CI, figs. 2a and 2b, respectively.)

Nisusia (Jamesella) perpasta subquadrata Pompeckj, WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 255. (Original description copied, and variety discussed as on p. 737.)

The original description by Pompeckj follows:

As compared with the type form, this variety is distinguished by less breadth, the length being to the breadth as 3 to 4. The anterior angles of the straight hinge edge are drawn in somewhat more than those of *Orthis perpasta*. The ventral valve is higher, with higher and steep area, pierced by a large triangular foramen. The sinus, which

^a Localities 345i and 345k are represented in the collections of the United States National Museum.

extends from the high vertical apex to the frontal edge, is bordered by obtusely rounded edges. Dorsal valve proportionally more bulged than in the type form. Sculpture as in *Orthis perpasta*.

The outer form strikingly recalls *Orthisina*; but the pseudodeltidium, the median septum, and the spondylium of the ventral valve are lacking.

Orthis perpasta var. *subquadrata* was found in several internal casts and impressions, together with *Orthis perpasta*, more rarely in graywacke sandstone than in the conglomerate-like, quartzitic sandstone.

Observations.—This variety apparently is not constant, as ventral valves occur in the material before me that have the subquadrated form with relatively less convexity than the convex forms of the species *perpasta*.

FORMATION AND LOCALITY.—**Lower Cambrian:** Conglomeratic sandstones and graywacke inclusions in the lower conglomerate zone of the Kamenná hůrka at the following localities [Pompeckj, 1896b, p. 516]: (345i) near Tejšovik; and (345j) at Gross Lohovic, southwest of Skrej; both in Bohemia, Austria-Hungary.

NISUSIA (JAMESELLA) SPENCEI (Walcott).

Text figure 62; Plate XCIII, figures 7, 7a.

Protorthis spencei WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 285. (Described as below as a new species.)

This is a strongly marked species, despite the fact that the few specimens that have been found are flattened in the shale. It is distinguished by its rounded, subquadrated outlines and narrow, sharp ribs with strong interspaces, six ribs in a distance of 5 mm. at the front margin. The area of the ventral valve has a broad delthyrium with a convex deltidium covering the greater part of it. The interior surface of the shell is finely punctate. A flattened ventral valve has a length of 17 mm.; width, 18 mm.

This shell is associated with *Nisusia (Jamesella) nautes* (Walcott). It differs from it in its larger size, sharper ribs, and broader interspaces between the ribs.

The discovery in the collection of 1907 of a specimen of a ventral valve showing a very perfect area and arched deltidium proves that the specimen upon which the reference to *Protorthis* was based had the deltidium crushed so that it was concave, thus causing it to be mistaken for the free spondylium of *Protorthis*.

The specific name is given in honor of Mr. R. S. Spence, of Evanston, Wyoming.

FORMATION AND LOCALITY.—**Middle Cambrian:** (55c and 163)^a *Spence shale member of the Ute limestone* [Walcott, 1908a, p. 8], about 50 feet (15.2 m.) above the Brigham quartzite and 2,755 feet (839.7 m.) below the Upper Cambrian, in a ravine running up into Danish Flat from Mill Canyon, about 6 miles (9.6 km.) west-southwest of Liberty and 15 miles (24.2 km.) west of Montpelier, Bear Lake County, Idaho.

(11q) About 2,350 feet (716.3 m.) above the Lower Cambrian and 2,050 feet (624.8 m.) below the Upper Cambrian in the limestone forming 1c of the Marjum limestone [Walcott, 1908f, p. 180], ridge east of Wheeler Amphitheater [Walcott, 1908f, Pls. XIII and XV], House Range, Millard County, Utah.

NISUSIA (JAMESELLA) UTAHENSIS Walcott.

Plate CI, figures 10, 10a.

Nisusia (Jamesella) utahensis WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 255-256. (Described and discussed as below as a new species.)

Ventral valve transverse, strongly convex; most elevated at the umbo, which is surmounted by the upward pointing apex at the edge of the area; area slightly inclined forward from the hinge line; delthyrium large and covered by a convex deltidium. Surface marked by several strong, rounded ribs irregularly alternating with smaller ribs; fine radiating striæ occur on the ribs and interspaces.

FIGURE 62.—*Nisusia (Jamesella) spencei* (Walcott). A, A', Exterior of ventral valve and view of cardinal area.

The specimen represented is from Locality 55c, Middle Cambrian Spence shale, near Liberty, Bear Lake County, Idaho (U. S. Nat. Mus. Cat. No. 52435a).

Only two specimens of somewhat imperfect ventral valves are known of this species. The description is of the best-preserved specimen. The second specimen has a greater number of more regular ribs that increase by interpolation of short ribs. The specimen illustrated has a width of 8 mm. and a length of 4.5 mm. from the apex to the front margin, which is about the distance from the hinge line to the front margin.

The nearest related species is *Nisusia alberta* (Walcott), from which it differs in surface ribs, forward inclination of the area, and prominent convex deltidium.

FORMATION AND LOCALITY.—Middle Cambrian: (7w) Limestone in Rock Canyon, in the Wasatch Mountains east of Provo, Utah County, Utah.

NISUSIA (JAMESELLA) sp. undt. Walcott

Nisusia (*Jamesella*) sp. undt., WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 256. (Characterized as below as an undetermined species.)

This doubtful species is based on an interior cast of a broken ventral valve. The width of the shell is 15 mm., and length 8 mm., with apex broken off. A broad, shallow sinus arches the frontal margin, and narrows toward the umbo. Radiating ribs narrow, about five in a space of 2 mm.

FORMATION AND LOCALITY.—Lower Cambrian: (392a) Limestone at L'Anse au Loup, on the north shore of the Straits of Belleisle, Labrador.

Genus PROTORTHIS Hall and Clarke.^a

[*πρὸς*, early; and *Orthis*.]

Protorthis HALL and CLARKE, 1892, Eleventh Ann. Rept. State Geologist New York for 1891, pp. 273-274. (Described as in first two paragraphs below.)

Protorthis HALL and CLARKE, 1892, Forty-fifth Ann. Rept. New York State Museum for 1891, pp. 589-590. (Copy of preceding reference.)

Kutorgina HALL and CLARKE [not WALCOTT], 1892, Nat. Hist. New York, Paleontology, vol. 8, pt. 1, pp. 90-94. (Copies Walcott's description, 1886b, pp. 101-102, and discusses genus, but description and discussion also include reference to specimens now referred to *Protorthis*, *Billingsella*, *Micromitra*, *Micromitra* (*Paterina*), and *Micromitra* (*Iphidella*).)

Protorthis HALL and CLARKE, 1892, idem, pp. 231-233. (Described and discussed as a new genus. With two omissions this reference is copied below.)

Billingsella Hall and Clarke, SCHUCHERT (in part), 1897, Bull. U. S. Geol. Survey No. 87, p. 158. (Characterized and discussed. The genus *Protorthis* is placed as a synonym of *Billingsella*, and among the species referred to the latter genus are species belonging with both *Protorthis* and *Nisusia*.)

Protorthis Hall and Clarke, WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 280-281. (Copies Hall and Clarke, 1892c, pp. 231-233, and discusses genus as on p. 739.)

Protorthis Hall and Clarke, GRABAU and SHIMER, 1907, North American Index Fossils, vol. 1, p. 211. (Characterized.)
Protorthis Hall and Clarke, WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 4, Pl. XI, and pp. 142 and 147. (Classification of genus.)

Hall and Clarke [1892c, pp. 231-233] described the species as follows:

Shells small, transversely subquadrate or semicircular. Hinge line straight, its length being equal to the greatest width of the valves. Valves unequally biconvex, or subplanoconvex, the pedicle valve being the larger. The cardinal area is narrow on both valves, but is higher on the (ventral) pedicle valve, and is transected by a broad delthyrium which is closed below by a concave plate apparently produced by the union of the dental lamellæ, which are not continued to the bottom of the valve; teeth distinctly developed. In the brachial (dorsal) valve the cardinal area also bears an open delthyrium; the dental sockets are obscure and the crural plates small; the latter appear to unite and form a low elevation across the base of the delthyrium. Cardinal process absent or rudimentary in all the specimens examined. Muscular markings in both valves extremely obscure.

^a The synonymy for this genus does not give a complete record of the various genera under which the species now included in *Protorthis* were formerly placed; it gives only those references in which the genus is discussed or described. To complete the record for the species taken up in the monograph the following mere generic references are listed:

Orthis Hartt [1868, p. 644; 1878, p. 644].
Orthis Walcott [1884a, p. 17].
Kutorgina Matthew [1886, p. 42].
Orthis Matthew [1886, p. 43].
Orthis Hartt [1891, p. 644].

Orthisina? Matthew [1891, p. 131].
Orthis (*Protorthis*) Wysogórski [1900, p. 227].
Protorthis (*Billingsella*) Grabau and Shimer [1907, p. 211].

Surface marked by distinct plications, with interstitial finer radii, which are crossed by delicate concentric striae; these are usually accompanied by a low sinus and fold on the brachial and pedicle valves, respectively; interior very finely papillose. Shell substance fibrous and apparently punctate.^a

The characters of the St. John species are eminently comprehensive; first, the form of the shell is one more frequently met with among the strophomenids than among the orthids; the concave plate formed by the union of the dental lamellæ is never found in *Orthis* proper, though occurring in *Scenidium*. In *Orthisina* or *Clitambonites* this plate is always present, but always supported by a median septum and invariably accompanied by the convex deltidium, which, so far as known, does not exist in *Protorthis*; while in the group typified by *Orthis pepina* Hall (here designated by the term *Billingsella*), the convex deltidium of *Clitambonites* is present and the concave or dental plate absent. The apparent absence of a cardinal process in *Protorthis* may be due to the imperfections of the fragile shells studied. The specimens of the St. John shells are preserved as external and internal casts, and from some of these there is reason to infer that the substance of the shell was punctate.

Type.—*Orthis billingsi* Hartt.

Observations.—A study of the various species here described under the genus *Protorthis* has not given data that will add to the above generic description. All of the species have evidence of punctæ of greater or less depth on the inner and outer surfaces of the shell, but in none of them have punctæ been found that penetrated through the shell; this may be owing largely to the fact that all of the species are preserved as casts in the sandstone or shale and none of them have the original shell substance or a calcareous or siliceous replacement of it.

A careful examination of a large number of specimens of the dorsal valve fails to reveal a true cardinal process.

PROTORTHIS BILLINGSI (Hartt).

Plate XCIX, figures 1, 1a-g.

Protorthis billingsi (Hartt), WALCOTT, 1905, *Proc. U. S. Nat. Mus.*, vol. 28, pp. 281-282. (Described and discussed as below.)

Protorthis (Billingsella) billingsi (Hartt), GRABAU and SHIMER, 1907, *North American Index Fossils*, vol. 1, p. 211, fig. 250. (Described. The five figures included in fig. 250 are all copied from Walcott, 1884a, Pl. I, figs. 1, 1a-d.)

The generic description follows very closely that of the type species *Protorthis billingsi* in its main features. All of the specimens are compressed in the embedding shale, which renders it difficult to get a true conception of the convexity and form of the valves. The general form is shown by the illustrations. The outline may be transversely quadrilateral or subsemicircular (Pl. XCIX, figs. 1 and 1e) or subquadrate (figs. 1a-f). Usually the beak is inclined backward over the area, but it may be distorted by pressure so as to appear to incline forward. Young shells have a well-defined median sinus on the ventral valve that shows as a flattened space on the larger shells. A slight sinus sometimes appears on the dorsal valve. The surface of the shell varies in the number and size of the radiating ribs; sometimes they are scarcely visible

^a The casts of the interior of the valves indicate that the inner layer of the shell is punctate, but I have been unable to obtain any evidence that the shell had the fibrous or punctate structure characteristic of *Dalmanella*.

toward the cardinal margin, and in other shells they are clearly defined all over the surface; the increase in number is by bifurcation and interpolation; fine, threadlike concentric striae and strong squamose lines of growth cross the ribs.

Ventral valve moderately convex, with the umbo and apex slightly curved over the area (Pl. XCIX, fig. 1), or erect above the area (Pl. XCIX, fig. 1b). The cardinal area appears to be slightly concave; divided midway by a triangular delthyrium, which is more or less closed by a concave plate that Hall and Clarke consider [1892c, p. 231] to be formed by the extension of the dental plates or lamellæ; from the casts it appears that the teeth were well developed and supported by dental plates that united at the center opposite the delthyrium, but did not reach the bottom of the valve or a median septum; the free spondylium varied in length from a narrow rim opposite the head of the delthyrium to a plate two-thirds or more of the length of the delthyrium.

Dorsal valve uniformly and moderately convex, with the apex curved over to the edge of the low area; area divided by a broad delthyrium; casts of the interior show that the cruræ were strong, dental sockets shallow, and that the crural plates extended across the umbonal cavity, uniting to define what may be called a pseudocruralium. No trace of a cardinal process has been seen in a large number of casts of the interior, and Hall and Clarke did not find any in a large amount of material.

The casts of the interior show that the inner layer of the shell was minutely punctate, and a shell preserving some of the inner layers has every appearance of such a structure.

Observations.—This species differs from all recognized species of the genus by its surface ribs and striae.

The specific name was given in honor of Mr. E. Billings.

FORMATION AND LOCALITY.—Middle Cambrian: (2e) Shale 25 feet (7.6 m.) above the basal quartzite, on Seeley Street, St. John; (3b) shale at the base of the *Paradoxides* zone, at the head of Seeley Street, St. John; (301k) St. John formation in the city of St. John; (301g) sandstones of Division 1c of Matthew, at Portland (now a part of the city of St. John); (308h and 308i) shales in Portland (now a part of the city of St. John); (301j) shales of the St. John formation at Ratcliff's Millstream; and (21 and 2m) limestone at the base of the *Paradoxides* zone [Matthew, 1895a, p. 108], on Hanford Brook; all in St. John County, New Brunswick, Canada.

PROTORTHIS HELENA Walcott.

Plate XCIX, figures 4, 4a-b.

Protorthis helena WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 282. (Characterized and discussed essentially as below as a new species.)

This species is founded on the cast of a ventral valve associated with *Trematobolus kempanum* (Matthew). The form of the spondylium and area is much like that of *Protorthis latourensis* (Matthew) (Pl. XCIX, figs. 3b and 4b), but the smooth shell with its broad, rounded mesial sinus is unlike that species and also other species of the genus. The shell appears to have been thicker than that of *P. latourensis*. Only traces of growth lines are preserved on the cast. The ventral valve is 10 mm. long, with a width of 14 mm. The cast shows that the teeth and dental plates were unusually strong.

This species differs from all others of the genus by its smooth or nearly smooth surface and strong median sinus. It suggests *Syntrophia barabuensis* (Winchell) at first sight, but there is no evidence of a median septum supporting the spondylium.

The specific name was given for Mrs. Walcott, who collected the specimen.

FORMATION AND LOCALITY.—Middle Cambrian: (2u) Lowest beds exposed on the south side of Long Island, Kennebecasis Bay [Matthew, 1898a, pp. 124 and 127], St. John County, New Brunswick, Canada.

PROTORTHIS? HUNNEBERGENSIS Walcott.

Plate XCV, figures 5, 5a-c.

Protorthis? hunnebergensis WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 284. (Described and discussed as on p. 741 as a new species. The name "*nunnebergensis*" was used under the impression that the correct spelling of the type locality was Nunneberg; the species occurs on Hunneberg.)

Protorthis? hunnebergensis Walcott, Moberg and Segerberg, 1906, Medd. från Lunds Geol. Fältklubb, Ser. B, No. 2 (Aitryck ur K. Fysiografiska Sällskapets Handl., N. F., Bd. 17), pp. 70-71, Pl. II, figs. 5, 5a-c. (Described and discussed. Figs. 5, 5a-c, in common with the remaining figures on Pl. II of Moberg and Segerberg's paper, were copied from a preliminary photograph of Pl. XCV of this monograph.)

Shell transversely semielliptical, plano-convex. Surface with very fine ribs that increase by interpolation and bifurcation; on some shells bands of slender ribs are delimited by stronger ribs, usually 2 to 5, between 2 more prominent ribs; fine concentric striæ give a crenulated aspect to the radiating ribs. Casts of the interior and exterior appear to be minutely papillose, indicating punctæ in the shell.

Ventral valve moderately convex, with the apex curved down to the margin of the area; area and interior unknown. Dorsal valve flat or very slightly concave between the umbo and margins; apex slightly elevated above the plane of the surface and cardinal line; a median sinus is present in some shells.

Observations.—It is a little hazardous to refer this species to *Protorthis*, as only the general form and surface are known. The nearly plano-convex valves and surface relate it more nearly to *Protorthis* than to *Plectorthis*, and it does not appear to fall within *Leptæna*, *Rafinesquina*, or *Strophomena*. The specimens were collected by Mr. Schmalensee in a dark, argillaceous shale above the *Ceratopyge* limestone and below the lower graptolite shale.

The specific name is derived from Hunneberg, Sweden.

FORMATION AND LOCALITY.—**Passage beds** between the Upper Cambrian and the Ordovician: (390f) Shales between the "lower graptolite slate" and the *Ceratopyge* limestone, at Mossebo, on Hunneberg, western boundary of the Province of Skaraborg, Sweden.

PROTORTHIS LÆVIS Walcott.

Plate XCIX, figures 6, 6a-b.

Protorthis lævis WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 283. (Described and discussed as below as a new species.)

Ventral valve transversely semicircular, moderately convex; surface of cast smooth; area overhanging the hinge line at about 30° from the plane of the margin of the valve. The cast shows a very clearly defined free spondylium. Shell about 6 mm. in width and 4 mm. in length.

This is one of the few representatives of the genus known outside of the Atlantic basin Cambrian fauna. Its smooth surface and inclined area distinguish it from other species of the genus.

FORMATION AND LOCALITY.—**Upper Cambrian:** (79a) "St. Croix sandstone" in a quarry and ledge 0.5 mile (0.8 km.) southeast of the county courthouse, Menomonie, Dunn County, Wisconsin.

PROTORTHIS LATOURENSIS (Matthew).

Plate XCIX, figures 3, 3a-d.

Kutorgina latourensis MATTHEW, 1886, Trans. Roy. Soc. Canada, vol. 3, sec. 4, No. 4, pp. 42-43, Pl. V, figs. 18, 18a-c. (Described and discussed. None of the specimens represented by figs. 18, 18a-c are figured in this monograph.)

Kutorgina latourensis (Matthew), HALL and CLARKE, 1892, Nat. Hist. New York, Paleontology, vol. 8, pt. 1, pp. 93, 95, and 233, Pl. IV, figs. 18-20. (Discussed.)

Protorthis latourensis (Matthew), WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 282-283. (Original description, Matthew, 1886, pp. 42-43, copied, and species discussed as on p. 742.)

The original description by Matthew follows:

Valves narrowly semicircular, broader than long, flat; umbones low; greatest thickness in the posterior third; hinge line shorter than the width of the shell.

Dorsal valve with a distinct median depression extending from the umbo to the front margin, and with low ridges diverging from the beak toward the lateral third of the front of the valve. Umbo not elevated above the hinge area, which is exceedingly narrow or absent. Hinge line with two sharp slightly projecting teeth near the umbo (crura?).

Ventral valve with a narrow median ridge extending two-thirds of the length of the valve toward the front margin; also with a fainter ridge on each side diverging toward the lateral third of the border of the valve; umbo very

low; hinge area perceptible, but very narrow, longitudinally striated, and having a minute tooth on each side of the very narrow and small foraminal opening.

Surface ornamented with about forty or fifty fine, faint, radiating striæ; those of the middle fifth are close, continuous, and straight; a few on each side of these are divergent, while those near the back of the shell are fainter, closer than the last, and moderately arched outward toward the lateral borders. The surface of the valves is also marked by very fine but distinct concentric striæ, and at somewhat regular intervals by about twelve more distinct lines of growth. The concentric striæ are usually as distinct as the radiating. Casts of the interior of the valves exhibit a smooth surface with some irregular, sinuous, radiating striæ.

Length, 7 mm.; width, 11 mm. Length of hinge line, 8 mm.

Observations.—Doctor Matthew kindly sent me the typical specimens of this species, and from them and specimens in the collections of the United States National Museum sufficient data were obtained to clearly show that the species belongs to *Protorthis* and not *Kutorgina*. In figure 3b, Plate XCIX, the free spondylium is present. As far as known, the characters of the area, teeth, and free spondylium are the same as in *P. billingsi*. The smooth casts suggest *Kutorgina* [Hall and Clarke, 1892c, Pl. IV, figs. 18–20], but the ribbed shells recall *P. quacoensis*, and the area with open delthyrium and free spondylium places the species in *Protorthis*. Its very fine surface ribs differentiate *P. latourensis* from all other described species.

The form described by Matthew [1886, p. 43, Pl. V, fig. 19] as "*Kutorgina pterineoides*" is not taken up in this monograph. The species is represented by one distorted specimen which may not even be a brachiopod.

FORMATION AND LOCALITY.—Middle Cambrian: (301w) *Shales of Division 1c2 of Matthew's section*; (308h) shales of Division 1cl of Matthew's section; and (301g) shales of Division 1c of Matthew; all at Portland (now part of the city of St. John), St. John County, New Brunswick.

PROTORTHIS QUACOENSIS (Matthew).

Plate XCIX, figures 2, 2a–e.

Orthis quacoensis MATTHEW, 1886, Trans. Roy. Soc. Canada, vol. 3, sec. 4, No. 4, pp. 43–44, Pl. V, figs. 20, 20a–c. (Described and discussed. The two specimens represented by figs. 20–20a and 20b–20c are redrawn in this monograph, Pl. XCIX, figs. 2e and 2b, respectively.)

Orthisina? quacoensis MATTHEW, 1891, Trans. Roy. Soc. Canada, 1st ser., vol. 8, sec. 4, No. 6, p. 131. (Mentioned and generic reference changed.)

Protorthis quacoensis (Matthew), HALL and CLARKE, 1892, Nat. Hist. New York, Paleontology, vol. 8, pt. 1, p. 232, Pl. VIIA, fig. 21. (Changes generic reference.)

Billingsella quacoensis (Matthew), SCHUCHERT, 1897, Bull. U. S. Geol. Survey No. 87, p. 159. (Merely changes generic reference.)

Protorthis quacoensis (Matthew), WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 284–285. (Original description, Matthew, 1886, pp. 43–44, copied and species discussed as below.)

The original description by Matthew follows:

A small species. Subquadrate to semielliptical in outline, broader than long, widest near or at the hinge line, which is not produced; moderately convex, highest in the posterior third, flattened toward the front and sides. Umbones not prominent.

The dorsal valve rises rapidly from the hinge line, and has but a narrow, flattened space at the angles. It is about one-third as high as it is long. The hinge plate has a narrow area, which is striated lengthwise, and bears two tooth-like processes close to the umbo, the point of which is bent down to the hinge line.

The ventral valve is somewhat more elevated than the dorsal. Hinge area triangular, sloping backward to the umbo, and bearing fine striæ parallel to the hinge line. Umbo elevated above the hinge line to a height fully equal to one-third of the length of the valve. Foramen (delthyrium) large, truncate-pyramidal in outline.

Surface of the valves ornamented by about twenty rounded plicæ, radiating (in the ventral valve) from the edge of the hinge area; opposite the foramen (delthyrium) and not from the beak alone; those on the middle fifth of each valve are crowded together; those outside of these are more prominent, and are continuous from the umbo; those toward the hinge line are faintly marked and widely separated. The radiating plicæ do not (or rarely) increase by bifurcation. Both valves bear numerous concentric striæ and are also marked by a few distinct squamose lines of growth.

The mold or cast of the interior of the valves of this species is nearly smooth, or is marked by faint radiating striæ; the margin of the mold, however, often exhibits a crenulated appearance corresponding to the plicæ of the outer surface. There is a wide, smooth median depression at the top of the mold of the dorsal valve, near the umbo.

Length of the valve in *O. quacoensis*, 5 mm.; width, 8 mm.

Observations.—Doctor Matthew very kindly sent me his types of this species and I have had a number of drawings made from them. A glance at them and the illustrations of *P. billingsi* shows that the two species are quite distinct and that *P. quacoensis* is unlike any other shell referred to the genus.

As far as seen, the free spondylium of the ventral valve is short; the teeth are clearly shown in the cast. The pseudocruralium of the dorsal valve is much more clearly defined than in *P. billingsi* (pc, Pl. XCIX, figs. 2c and 2e), the area is higher (Pl. XCIX, fig. 2c), and traces of the adductor muscle scars are preserved (Pl. XCIX, fig. 2d).

FORMATION AND LOCALITY.^a—Middle Cambrian: (301m [Matthew, 1886, p. 44]) Shale of Division 1c of Matthew's section on Porters Brook, St. Martins; (3b) shale at the base of the *Paradoxides* zone, at the head of Seeley Street, St. John; (301w) shales of Division 1c2 of Matthew's section at Portland (now a part of the city of St. John); and (301g [Matthew, 1886, p. 44]) sandstones of Division 1c at Portland (now part of the city of St. John); all in St. John County, New Brunswick, Canada.

PROTORTHIS WINGI Walcott.

Plate XCIII, figures 5, 5a-c.

Protorthis wingi WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 286. (Described and discussed as below as a new species.)

General form transversely subelliptical. Surface marked by about 20 sharply ridged ribs, with interspaces equal and usually greater than the width of the rib; shell with numerous small and many larger and scattered punctæ on the inner and outer surfaces. The largest ventral valve has a length of 6 mm.; width, 9 mm.

Ventral valve convex, elevated at the umbo and beak; area high and divided midway by a strong delthyrium, which is partly closed by a concave free spondylium (sp) as in *P. billingsi*; teeth strong, dental plates extended toward the center to unite and form the free spondylium.

Dorsal valve slightly convex, with a broad median sinus that is usually bounded by one or two large ribs; casts of the interior show a narrow area, broad delthyrium, and, opposite the umbo, the cast of a small, broadly triangular, elevated area that probably served as the cardinal process for the attachment of the diductor muscles.

Observations.—This species is most nearly related to *Nisusia (Jamesella) nautes* (Walcott); it differs, as far as known, in the character of the interior of the dorsal valve, the large punctæ scattered among the fine punctæ, and the sharp-ridged ribs. One cast of an interior of a ventral valve (Pl. XCIII, fig. 5a) appears to indicate that the shell was without the free spondylium; it not infrequently occurs in *Protorthis billingsi* (Hartt) that the free spondylium is reduced to a narrow rim about the margin of the delthyrium and it may be that in this shell it was absent.

The specific name is given in memory of Rev. Augustus Wing, whose extensive and excellent work in the vicinity of Swanton, Vermont, was utilized by Billings and Logan in the reports of the Geological Survey of Canada.

FORMATION AND LOCALITY.—Upper Cambrian: (28) Shales about 100 feet (30.5 m.) above the *Olenellus* horizon south of Highgate Falls, 0.25 mile (0.4 km.) east of Swanton, Franklin County, Vermont.

PROTORTHIS sp. undt. Walcott.

Protorthis sp. undt., WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 286. (Described and discussed as below as an undetermined species.)

Ventral valve convex, elevated at the umbo, apex incurved. The cast of the umbonal cavity (pseudospondylium) indicates well-developed teeth and dental plates. On the cast six radiating ribs occur in the distance of 1 millimeter; area about vertical. The surface of the cast indicates that the interior layer of the shell was finely punctate. Length of valve 4.5 mm.; width, 5.5 mm.

^a Matthew does not state which of the two localities, 301g and 301m, is the type, though he [1886, p. 82] locates the type specimen (Pl. XCIX, fig. 2b) in Division 1c of his Etcheminian.

Only one specimen of a cast of a ventral valve of this shell was found. It suggests by its convexity and surface some of the more convex forms of *Protorthis quacoensis*

FORMATION AND LOCALITY.—Upper Cambrian: (75) Thin-bedded limestone just below the base of the Ordovician, in the Tonto group; near the water's edge at the mouth of Kanab Canyon, Grand Canyon of the Colorado, Arizona.

LOPERIA Walcott, subgenus of **PROTORTHIS**.

Protorthis (Loperia) WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 287. (Characterized as below as a new subgenus.)

Protorthis (Loperia) WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 4, Pl. XI, and pp. 142 and 147. (Classification of subgenus.)

This subgenus is characterized by the form of the valves. The ventral valve is elevated at the umbo and flat or slightly concave from the umbo to the margins; the dorsal valve is strongly and regularly convex. The description of the type species, *Protorthis (Loperia) dugaldensis* Walcott, includes that of the subgenus, as it is the only species thus far known.

The subgeneric name is given in recognition of the effective work of Mr. S. Ward Loper, who collected the material representing this and many other Cambrian fossils in Cape Breton and New Brunswick.

PROTORTHIS (LOPERIA) DUGALDENSIS Walcott.

Plate XCIX, figures 5, 5a-j.

Protorthis (Loperia) dugaldensis WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 287-288. (Described and discussed as below as a new species.)

General form rounded subquadrate. Hinge line straight and shorter than the greatest width of the shell; cardinal extremities obtusely angular. Relative convexity of the valves reversed as in *Dinorthis pectinella* [Hall and Clarke, 1892c, Pl. V, figs. 28-31] of the Ordovician fauna. Surface of the valves with strong, simple, rounded ribs that increase by interpolation; fine concentric striæ and lines of growth, that sometimes form ridges, cross the ribs, curving in the interspaces and over the ribs; these ribs are more prominent and numerous (30 to 40) on the dorsal than on the ventral valve; on the latter the ribs are broad, with narrow interspaces, and about 20 to 25 in number; casts of the exterior and interior surfaces have numerous fine, thickly set, elevated papillæ that appear as the casts of the punctæ in the layers of the shell; on some specimens the papillæ are cylindrical and elevated, which indicates that they penetrated deep into the shell substance. All indications point to a punctate shell; in all the material representing the species the shell has been removed by solution, only the casts of the inner and outer surfaces remaining.

The largest ventral valve in the collection has a length of 18 mm., width 25 mm.; dorsal valve, length 22 mm., width 27 mm.

Ventral valve elevated at the umbo and gently concave from the umbo to the front margin and flat to the cardinal extremities. Area relatively low and overhanging the hinge line at an angle of about 45°; it is divided midway by a broad delthyrium that is more or less closed by a deeply concave plate, which is crossed by the transverse striæ of growth of the area. The concave plate appears to be identical in form and position with the free spondylium of the genus *Protorthis*. A cast of the interior (fig. 5) shows very strong teeth and supporting dental plates; the edges of the dental plates appear to be continuous with the concave plate or free spondylium.

Dorsal valve strongly and regularly convex, with a slight flattening of the median line and sometimes a shallow sinus. Casts of the interior show a strong area, with a triangular delthyrium; the umbonal cavity is strongly outlined by the crural plates so as to form a pseudo-cruralium; crura well developed, with clearly defined tooth sockets back of them. No traces of a cardinal process have been seen in ten specimens showing fine casts of the area, delthyrium, and umbonal cavity.

Observations.—This fine species is unique among Cambrian brachiopods in having a depressed, flat, or convex ventral valve and strongly convex dorsal valve; in its punctate

shell, free spondylium and absence of cardinal process, it is allied closely to *Protorthis*; the depressed ventral valve and convex dorsal valve serve to distinguish it as a subgenus of *Protorthis*.

The specific name is derived from Dugald Brook, Cape Breton.

FORMATION AND LOCALITY.—Middle Cambrian: (10p) Sandstone just below the waterfall 0.25 mile (0.4 km.) from the lower bridge in Division E2b of Matthew's [1903, p. 21] Etchemanian, Dugald Brook, Indian River, eastern Cape Breton, Nova Scotia.

(2u) Lowest beds exposed on the south side of Long Island, Kennebecasis Bay [Matthew, 1898a, pp. 124 and 127], St. John County, New Brunswick.

Subfamily BILLINGSSELLINÆ Schuchert.

Genus WIMANELLA Walcott.

Billingsella WALCOTT (in part) [not HALL and CLARKE], 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 227-229. (Described and discussed as on p. 749 (under *Billingsella*), but several of the species referred to the genus are now placed under *Wimanella*.)

Wimanella WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 3, pp. 98-99. (Discussed somewhat as below as a new genus.)

Wimanella WALCOTT, 1908, idem, vol. 53, No. 4, Pl. XI, and pp. 142 and 148. (Classification of genus.)

This genus is proposed for the smooth nonplicate species that I have heretofore referred to the genus *Billingsella*. The generic description of *Billingsella* includes the characters of *Wimanella* with the exception that the latter is a smooth shell but for the presence of concentric striæ and lines of growth. *Wimanella* represents the smooth, early stages of development and *Billingsella* the later, mature plicate stage of development of this section of the Billingsellidæ.

Type.—*Wimanella simplex* Walcott [1908d, p. 98].

Observations.—It is to be noted that *Billingsella plicatella* Walcott (Pl. LXXXVI, figs. 3g and 3h) includes some shells that are nearly smooth, and that *B. highlandensis* (Walcott) (Pl. LXXXVII, figs. 4 and 4c) is very finely costate. The former species may be considered as being in part a form intermediate between *Billingsella coloradoensis* (Shumard) and *Wimanella harlanensis* (Walcott). I think, however, that the species with smooth shells should be grouped under a generic head, as they indicate a marked phase in the evolution of the forms formerly grouped under *Billingsella*.

The generic name was given in recognition of the valuable work of Dr. Carl Wiman of the University of Upsala, on the geology and paleontology of the Baltic region.

WIMANELLA? ANOMALA (Walcott).

Plate LXXXVII, figures 1, 1a-e.

Billingsella? anomala WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 230. (Described and discussed as below as a new species.)

Shell subquadriangular, with the dorsal valve transverse. On the ventral valve the cardinal line slopes toward the beak at an angle of from 15° to 20°, while in the dorsal valve it is nearly straight. The greatest width of the valves is about the middle of the shell. Owing to compression and consequent distortion there is considerable variation in the relative proportions of length and breadth. The cardinal angle is acute, in some instances extending out some distance beyond the widest portion of the shell, resembling in this respect the cardinal angles of some of the Strophomenidæ. All of the specimens are so compressed in the shale that little is preserved of their natural convexity. A low, broad, mesial sinus occurs on the dorsal valve, and there is a slight flattening of the anterior central portion of the ventral valve.

The surface is marked by fine, radiating striæ, that are increased in number toward the front by the addition of interstitial striæ, giving a fasciculate appearance to the surface. The radiating striæ are crossed by concentric lines of growth and fine striæ. The surface as described occurs in one specimen, all other specimens being nearly smooth. This, however, may arise

from maceration and flattening out of the surface characters by compression. The interior of the shell appears to have been covered by minute punctæ.

The largest specimen of the collection has a transverse diameter of 14 mm. The average size of the ventral valve is about 8 mm. in height by 8 mm. in width.

Cardinal area about one-fifth the height of the shell. It is marked by transverse striæ of growth that cross it parallel to its base. Delthyrium rather broad. No traces of the deltidium have been observed. Cardinal area of the dorsal valve short. It is divided midway by a strong delthyrium. Nothing is known of the interior characters except the presence of a short crura in the dorsal valve.

Observations.—This shell occurs quite abundantly in the very fine, buff-colored, argillaceous shales of the Coosa Valley Cambrian section. There is some doubt as to its surface characters, as only one specimen found in the same beds has traces of radiating striæ, and these may be from the interior radiating lines. All others appear to be nearly smooth. Its strongest character is the extension of the cardinal angle. Owing to the imperfection of the material the generic reference is doubtful.

The species was anomalous while under *Billingsella*, to which it was first referred, hence the specific name.

FORMATION AND LOCALITY.—Middle Cambrian: (90) Conasauga ("Coosa") shale, on Edwards farm, near Craigs Mountain, about 10 miles (16.1 km.) southeast of Center, Cherokee County, Alabama.

WIMANELLA HARLANENSIS (Walcott).

Plate LXXXVII, figures 5, 5a-d.

Billingsella harlanensis WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 236. (Characterized and discussed as below as a new species.)

The general form and convexity of this shell is similar to that of *Billingsella plicatella* Walcott. It differs in having a nearly smooth surface marked only by fine concentric striæ and a few traces of narrow, sharp radiating costæ. The interior of the ventral valve has very strong main vascular sinuses and a deep, sharply defined, tripartite umbonal area opposite the delthyrium; the tripartite area is much like that in *Billingsella coloradoensis* (Shumard) and *B. exporrecta* (Linnarsson). The main vascular sinuses pass directly back across the ridge in front of the tripartite area and occupy the two lateral divisions of the area. The interior of the dorsal valve represented in figure 5a shows an abnormal arrangement of the vascular markings and muscle scars.

The specific name is derived from Harlan Knob, Tennessee.

FORMATION AND LOCALITY.—Middle Cambrian: (107) Limestone in Bull Run, northwest of Copper Ridge [Keith, 1896b, areal geology sheet], 11 miles (17.6 km.) northwest of Knoxville, Knox County; and (121) *Rogersville shale, road just east of Harlan Knob, 4 miles (6.4 km.) northeast of Rogersville* [Keith, 1905, areal geology sheet], Hawkins County; both in Tennessee.

WIMANELLA INYOENSIS Walcott.

Text figures 63A-B, page 747.

Wimanello inyoensis WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 3, p. 99, Pl. X, fig. 4. (Described as below as a new species. Fig. 4 is copied in this monograph as fig. 63A.)

This species is represented by numerous specimens in the form of casts in a calcareous sandstone. All of the shells are more or less compressed and distorted. Some of those best preserved indicate that the general outline was transverse. A specimen 6 mm. in length has a width of 7 mm. The two specimens illustrated (figs. 63A and 63B) occur on the same fragment of rock and illustrate fairly well the difference in outline; it may be that figure 63A is the narrow ventral valve and figure 63B the broader dorsal valve.

The most striking feature is the presence of two strong radiating ridges that originate near the beak and extend forward nearly to the frontal margin. These ridges may be the casts of the main vascular sinuses or it may be that they represent ridges on the exterior of the shell, one on each side of the shallow median sinus. At present, with the material before me, I am inclined to the view that they represent the casts of sinuses and hence the provisional generic reference to *Wimanella*.

Nothing is known with certainty of the outer surface or of the substance of the shell. The interior casts and the matrices of the casts show two strong radiating ridges, the shell substance having apparently been removed and its place lost by the compression of the sediment before its consolidation.

The specific name is derived from Inyo County, California.

FORMATION AND LOCALITY.—Lower Cambrian: (8b) Limestones in Tollgate Canyon, about 15 miles (24.2 km.) east of White Pine, White Mountain Range, Inyo County, California.

WIMANELLA SAFFORDI (Walcott).

Plate LXXXVII, figures 7, 7a.

Billingsella saffordi WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 244. (Described and discussed as below as a new species.)

General outline of ventral valve subsemicircular and of dorsal valve transversely broad oval; greatest width of valves at about the center; hinge line straight and a little shorter than the greatest width of the shell. A typical ventral valve has a length of 9 mm., width 9 mm. Dorsal valve, length 10 mm., width 12 mm. Biconvex, the ventral valve being more elevated at the umbo than the dorsal. Surface, so far as known, smooth or marked by concentric striae and lines of growth.

Ventral valve with umbo curving over and terminating in the small apex that incurves a little over the area; area about one-half the elevation of the valve; a broad delthyrium is partly covered by a convex deltidium; casts of the interior indicate a low, tripartite pseudospondylium and one cast shows strong main vascular sinuses extending from the lateral divisions of the pseudospondylium nearly to the front margin. Dorsal valve with low area and small pseudo-cruralium; the casts are too imperfect to show any other details.

Observations.—This species occurs in the same region as *Wimanella harlanensis* (Walcott) and also has a smooth shell; it differs in being of equal length and breadth and in having less strongly marked interior characters.

The specific name is given in recognition of the work of Mr. J. M. Safford upon the geology of Tennessee.

FORMATION AND LOCALITY.—Middle Cambrian: (14a) Sandstone of the Rome formation, along First Creek Gap, 4 miles (6.4 km.) north-northeast of Knoxville [Keith, 1905, areal geology sheet], Knox County, Tennessee.

WIMANELLA SHELBYENSIS Walcott.

Plate II, figures 9, 9a.

Wimanella shelbyensis WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 3, p. 100, Pl. X, fig. 3. (Described and discussed as below as a new species. Fig. 3 is copied in this monograph, Pl. II, fig. 9.)

All the specimens representing this species in the collection are flattened in the shale to such an extent that very little of the original convexity of the shell is retained, and only the impression of the shell remains, as the shell substance has been entirely removed, probably by solution. The general form of this species resembles very closely that of *Billingsella? appalachia*.

FIGURE C3.—*Wimanella inyoensis* Walcott. A, B, Narrow and broad forms showing the two strong ridges on the cast that are supposed to represent the main vascular sinuses (U. S. Nat. Mus. Cat. Nos. 52255a and 52255b, respectively).

The specimens represented are from Locality 8b, Lower Cambrian, Inyo County, California. Figure 63A is copied from Walcott [1908d, Pl. X, fig. 4]. It represents the type specimen.

The casts show a strong cardinal area on the ventral valve, with a broad delthyrium, but not a pseudodeltidium; the dorsal valve has a narrow cardinal area with a broad open delthyrium.

The exterior surface is marked by fine concentric lines and a few stronger varices of growth. A small ventral valve has a length of 8 mm., with a width of 10 mm. A larger one has a length of 18 mm.; width, 22 mm. A small dorsal valve has a length of 10 mm.; width, 13 mm.; and the largest dorsal valve in the collection has a length of 19 mm.; width, 25 mm.

None of the specimens show any traces of vascular or muscular markings; in this respect resembling *Wimanelia? anomala* (Walcott) (Pl. LXXXVII) and *Billingsella? appalachia* Walcott (Pl. LXXXVII).

This species appears to be the Lower Cambrian representative of *W.? anomala* of the Middle Cambrian, differing from the latter in having rounded cardinal angles instead of the acute projecting angles so characteristic of *W.? anomala*. *Billingsella? appalachia* has the same general form as *W. shelbyensis*, but the latter differs from it in having a smooth surface and in the absence of all traces of radiating ribs.

It more nearly resembles *Wimanelia simplex* Walcott (Pl. LXXXIX, fig. 2). It differs from the latter in being more transverse, and the cast of the umbonal cavity is relatively smaller.

It is a curious fact that in all the species of *Wimanelia* mentioned there is no trace of a vascular marking or muscle scar. All the species occur in argillaceous shale, and none of them preserve the shell substance. The shells appear to have been macerated and removed by solution, leaving only a cast of the compressed inner or outer surface of the valve.

The specific name is derived from Shelby County, Alabama.

FORMATION AND LOCALITY.—**Lower Cambrian:** (17b) *Shale in Rome ("Montevallo") formation, 4 miles (6.4 km.) south of Helena;* and (56c) shale in Rome ("Montevallo") formation along road just north of Buck Creek, 1.125 miles (1.8 km.) northeast of Helena; both in Shelby County, Alabama.

WIMANELLA SIMPLEX Walcott.

Text figure 64; Plate LXXXIX, figures 2, 2a-e.

Wimanelia simplex WALCOTT, 1908f, Smithsonian Misc. Coll., vol. 53, No. 3, p. 101, Pl. X, fig. 2. (Discussed as below as a new species. Fig. 2 is copied in this monograph, Pl. LXXXIX, fig. 2.)

The general form of this species is much like that of *Billingsella coloradoensis*, except that the beak of the ventral valve rises above the hinge line, much as in *B. highlandensis* (Pl. LXXXVII, figs. 4, 4a). The surface of *W. simplex* appears to be smooth except for a few concentric lines of growth. Nothing is known of the interior except what is shown by the cast of the umbonal cavity. A crushed specimen with the two valves flattened out (fig. 2e) indicates that the beak of the dorsal valve was slightly elevated above the hinge line; it is probable that figure 2 represents a dorsal valve. All the specimens are flattened in shale, and the shell substance has been removed by solution. The material is unsatisfactory, but as it represents a species of the smooth type from a known horizon in the Middle Cambrian, it is illustrated and given a specific name.

FIGURE 64.—*Wimanelia simplex* Walcott. Interior of a compressed dorsal valve. Found in Locality 35c, in a drift block of Lower Cambrian shale on Mount Bosworth, British Columbia (U. S. Nat. Mus. Cat. No. 51407).

FORMATION AND LOCALITY.—**Lower Cambrian:** (4v) About 200 feet (61 m.) above the unconformable base of the Cambrian and 75 feet (22.9 m.) above the top of the quartzitic sandstones in a shale which corresponds in stratigraphic position to shale No. 6 of the Dearborn River section [Walcott, 1908f, p. 202], Gordon Creek, 6 miles (9.6 km.) from South Fork of Flathead River; and (4q and 4w) about 315 feet (96 m.) above the unconformable base of the Cambrian and 190 feet (57.9 m.) above the top of the quartzitic sandstones in a shale which corresponds in stratigraphic position to shale No. 6 of the Dearborn River section [Walcott, 1908f, p. 202], on Youngs Creek, about 5 miles (8 km.) from its junction with Danaher Creek; both in the Ovando quadrangle (U. S. Geol. Survey), Powell County, Montana.

(35c) Drift blocks of siliceous shale supposed to have come from the Mount Whyte formation [Walcott, 1908f, p. 214], found on the south slope of Mount Bosworth, a short distance northwest of the Canadian Pacific Railway track between Stephen and Hector, eastern British Columbia, Canada.

Genus *BILLINGSSELLA* Hall and Clarke.^a

- Billingsella* HALL and CLARKE, 1892, Eleventh Ann. Rept. State Geologist New York for 1891, p. 273. (Described.)
- Billingsella* HALL and CLARKE, 1892, Forty-fifth Ann. Rept. New York State Museum for 1891, p. 589. (Copy of preceding reference.)
- Kutorgina* HALL and CLARKE [NOT WALCOTT], 1892, Nat. Hist. New York, Paleontology, vol. 8, pt. 1, pp. 90-94. (Copies Walcott's description, 1886b, pp. 101-102, and discusses genus, but description and discussion also include reference to specimens now referred to *Billingsella*, *Protorthis*, *Micromitra*, *Micromitra* (*Paterina*), and *Micromitra* (*Iphidella*.)
- Billingsella* HALL and CLARKE (in part), 1892, idem, pp. 230-231. (Described and discussed as a new genus. The genus as described also included species now referred to *Nisusia*.)
- Billingsella* Hall and Clarke, SCHUCHERT (in part), 1897, Bull. U. S. Geol. Survey No. 87, p. 158. (Characterized and discussed. The genus *Protorthis* is placed as a synonym of *Billingsella*, and among the species referred to the latter genus are species belonging with both *Protorthis* and *Nisusia*.)
- Billingsella* Hall and Clarke, WALCOTT (in part), 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 227-229. (Described and discussed essentially as below. Species that are now referred to *Wimanella* were included in the genus.)
- Billingsella* Hall and Clarke, GRABAU and SHIMER, 1907, North American Index Fossils, vol. 1, p. 210. (Described.)
- Billingsella* Hall and Clarke, WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 4, Pl. XI, and pp. 142 and 148. (Classification of genus.)

Shell subquadrate or subsemicircular in outline. Contour unequally biconvex or plano-convex. Shell impunctate. Surface striate or plicate. Ventral valve with the greatest convexity; cardinal area moderately high, slightly inclined outward; delthyrium covered by a convex plate which in the type species *B. coloradoensis* has a minute perforation near the apex; teeth well developed, with dental plates extending to the bottom of the umbonal cavity and forming the sides of a small area opposite the delthyrium, where the pedicle muscle was probably attached. In the dorsal valve the cardinal area is strongly inclined, but less than 90° to the plane of the valve. The delthyrium is partly covered by a convex chilidium, or it may be altogether absent. Cardinal process single. A rudimentary spondylium is indicated for *B. dice*. Shell structure dense, minutely granular, with minute pores scattered through the calcareous lamellæ.

Type.—*Orthis coloradoensis* Shumard.

Observations.—Hall and Clarke [1892c, p. 230] founded the genus on "*Orthis pepina*" Hall, which is a synonym of "*Orthis coloradoensis*" Shumard. The material from the limestones of Texas in the United States National Museum shows the form of the teeth in the ventral valve, also the deltidium and the minute perforation near its apex. Hall and Clarke [1892c, p. 230] state in their diagnosis that "in rare instances (it) may be minutely perforated at the apex," but do not name the species in which the perforation occurs or where the specimens showing it are to be found. All the species known to me are biconvex or plano-convex; none are concavo-convex as defined by Hall and Clarke [1892c, p. 230].

The genus is essentially orthoid, but it differs in the presence of the arched deltidium and its general aspect from typical examples of the Orthidæ, and its shell is of a dense, nonfibrous structure.

^a The synonymy for this genus does not give a complete record of the various genera under which the species now included in *Billingsella* were formerly placed; it gives only those references in which the genus is discussed or described. To complete the record the following mere generic references are listed:

Orthis Barrande [1848, p. 203].
Orthis Shumard [1860, p. 627].
Orthis Hall [1863, p. 134; 1867, p. 113].
Orthis Davidson [1868, p. 314; 1869, p. 230].
Orthis Linnarsson [1876, pp. 10, 12, and 13].
Orthis Barrande [1879b, Pl. LXII, fig. 11].
Orthis Whitfield [1882, p. 170].
Orthis? (*Orthisina?*) Hall [1883, Pl. XXXVII, figs. 16-19].
Orthis Kayser [1883, p. 35].
Kutorgina Walcott [1884b, p. 18].
Orthisina Whitfield [1884, p. 144].
Orthis? Walcott [1886b, p. 119].
Orthisina Walcott [1886b, p. 120].

Orthis Walcott [1887, p. 190].
Orthis Oehlert [1889, p. 1139].
Orthis? Walcott [1891a, p. 612].
Orthisina Walcott [1891a, p. 613].
Clitambonites (*Gonambonites*) Matthew [1895b, p. 267].

Orthis Pompeckj [1896b, p. 513].
Orthis (*Billingsella*) Sardeson [1896, p. 96].
Clitambonites Schuchert [1897, p. 184].
Billingsella Walcott [1899, p. 450].
Billingsella Matthew [1903, p. 145].
Orthis (*Plectorthis*) Walcott [1905a, p. 270].
Billingsella Walcott [1905d, pp. 101 and 102].

Of the species referred to the genus, *Billingsella exprorecta* is one that departs from the typical species in the absence of a strong convex deltidium, and *B. dice* has a rudimentary spondylium in the ventral valve, a character not developed in other species of the genus.

For the relations of *Billingsella* to *Nisusia*, see remarks under the latter genus, page 725. The genus was named in honor of Mr. E. Billings.

BILLINGSELLA? APPALACHIA Walcott.

Plate LXXXVII, figures 2, 2a-b.

Billingsella? appalachia WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 231. (Described as below as a new species.)

The outline of the dorsal valve is rounded subquadrate. The height and width of the ventral valve are about the same. Dorsal valve slightly transverse.

The surface is marked by round, very fine, radiating costæ, and lines of growth, with very fine interstitial concentric striae.

The average ventral valve is about 10 mm. in height, with an equal width. The largest shell observed was a ventral valve with a width of 14 mm.

Cardinal area of the ventral valve rather low. It is divided midway by a rather strong delthyrium.

Observations.—In form and size this shell is much like that of *Wimanelia? anomala*. It differs in its strongly marked surface characters. All the specimens are flattened in the shale and nothing is known of the interior characters.

FORMATION AND LOCALITY.—Middle Cambrian: (121) *Rogersville shale, road just east of Harlan Knob, 4 miles (6.4 km.) northeast of Rogersville [Keith, 1905, areal geology sheet], Hawkins County, Tennessee.*

This species is somewhat doubtfully identified from the following locality:

Middle Cambrian: (14) Limestones overlying the sandstones of the Rome formation, near the wagon road and in a quarry near the railroad track, 7 miles (11.2 km.) southwest of Rome [Hayes, 1902, historical geology sheet], Floyd County, Georgia.

BILLINGSELLA BIVIA n. sp.

Text figures 65A-C.

The specimens of this species are preserved in a sandstone and usually occur in the form of flattened casts. The valves are transverse in outline, equally convex, and have their greatest width at the hinge line. The beak of the ventral valve projects over the hinge line and

FIGURE 65.—*Billingsella bivia* n. sp. A, A', Top and side view of exfoliated dorsal valve, the type specimen, from Locality 141, Lower Cambrian, near Resting Springs, Inyo County, California (U. S. Nat. Mus. Cat. No. 52254a). B, Enlargement (X about 6) of the outer surface, with strong and fine radiating ribs, of a shell from Locality 14p, Lower Cambrian, near Resting Springs, Inyo County, California (U. S. Nat. Mus. Cat. No. 51404). C, Ventral valve from Locality 141, Lower Cambrian, near Resting Springs, Inyo County, California (U. S. Nat. Mus. Cat. No. 52254b).

is flattened so that it barely rises above the plane of the margins of the shell. The hinge line of the dorsal valve is broadly rounded, and most of the specimens show a fairly well marked mesial sinus. A dorsal valve preserving the outer surface shows it to have been covered by coarse, radiating costæ, each of which is marked by a number of minute radiating ridges.

The species is closely related to *Billingsella highlandensis* (Walcott), but differs from that species in being more transverse in outline, in the absence of a concentric striation, and in other details of surface sculpture, and in the prominence of the mesial sinus.

FORMATION AND LOCALITY.—Lower Cambrian: (141) Sandstones about 2,800 feet (853 m.) below the Middle Cambrian in a horizon correlated with No. 2] of the Silver Peak group of the Waucoba Springs section [Walcott, 1908f, p.

187], in the pass about 7 miles (11.2 km.) east of Resting (Freshwater) Springs; and (14p) sandstones near Resting (Freshwater) Springs; both in the southwest corner of T. 21 N., R. 8 E., on Amargosa River, in the southeastern part of Inyo County, California.

BILLINGSSELLA COLORADOENSIS (Shumard).

- Billingsella coloradoensis* (Shumard), WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 231-234. (Described and discussed essentially as below.)
- Billingsella coloradoensis* (Shumard), GRABAU and SHIMER, 1907, North American Index Fossils, vol. 1, p. 210. (Characterized.)

Shell usually transverse but in many examples the ventral valve is longer than wide. The general outline is irregularly subquadrate to subsemicircular. On the ventral valve the hinge line slopes toward the beak at a low angle while in the dorsal valve it is nearly straight. In some individuals the greatest width is at the hinge line. In others it is at about the middle. There is considerable variation in the relative proportions of length and breadth.

The ventral valve is slightly more convex than the dorsal. The degree of convexity of the two valves varies considerably in specimens from different localities. Some of the ventral valves from beds at Franconia, Minnesota, and the young shells from Trempealeau, Wisconsin, are strongly convex.

A low, broad, median sinus occurs on nearly all specimens of the dorsal valve, being straight in the young shells, and occasionally a shallow sinus is clearly defined on the ventral valve. It is quite rare to find a well-marked median fold on the ventral valve.

The surface is marked by sharply rounded, radiating costæ crossed by fine concentric lines of growth and very fine, slightly undulating, concentric striæ. The size and sharpness of the radiating ribs vary greatly in specimens from the same bed at the typical locality in Texas. Shells occur with strong rounded costæ, and no traces of fine elevated lines between, whereas others show from one to four or more lines that start at varying distances from the beak. The imbricating lines of growth give a concentrically ridged aspect to some shells, though others are nearly smooth from beak to frontal margin. The increase in the number of ribs is by interpolation, not by bifurcation.

There is considerable variation in the size of the shell. The largest specimens from Texas have a transverse diameter of 19 mm., with a length of 14 mm. for the dorsal valve, and about 18 mm. for the ventral valve. Specimens of the ventral valve from the Yellowstone National Park have a length of 14 mm. with a width of 15 mm.

FIGURE 66.—*Billingsella coloradoensis* (Shumard). Posterior view of a ventral valve showing pedicle opening in the deltidium; from Locality 70, Upper Cambrian, on Morgans Creek, Texas (U. S. Nat. Mus. Cat. No. 34777a).

Cardinal area of ventral valve moderately high. It is marked by transverse striae of growth that cross it parallel to its base and arch over the convex deltidium. The plane of the area extends backward at an angle of about 10° to the plane of the margin of the shell. The delthyrium is strong and covered by a convex deltidium, the front margin of which arches back about one-fifth the length of the delthyrium. The deltidium is marked by concentric striae of growth and fine radiating lines and a minute perforation near its apex. The cardinal area of the dorsal valve is short as compared with the ventral valve. It extends backward at an angle of about 45° to the plane of the margin of the valve. It is divided midway by a strong delthyrium which is covered for about half its distance by a convex chilidium.

In the interior of the ventral valve the hinge teeth appear to be supported by dental plates that extend down to the bottom of the valve and bound the tripartite umbonal space opposite the delthyrium into which the vascular sinuses extend on each side of the diductor muscle impressions, or their path of advance. The traces of the vascular system are confined to the main vascular trunks which extend forward nearly to the front margin, where in some examples they are bifurcated. The inner branch extends in toward the median line, disappearing in the numerous radiating depressions near the margin. The lateral branches appear to connect with the peripheral canal that arches about the space probably occupied by the ovarian areas, between itself and the main vascular trunks. The space for the attachment of the muscles between the main vascular trunks appears to have been quite large, extending forward to the anterior fifth of the length of the valve, but no subdivisions indicating the points of attachment of the different muscles have been detected. The pedicle muscles were probably attached to the elevated, posterior portion of this central area. In some casts this posterior area is scarcely elevated above the plane of the interior. In others it is fairly prominent.

In the interior of the dorsal valve the interior of the deltidial cavity supports a small well-developed cardinal process or callosity, and a slight narrow median ridge occurs just in advance of the deltidial cavity. The crura are short and well defined, with relatively shallow dental sockets beside them. The cardinal process and crura vary in size and length in shells from the same locality. The only traces of the muscle scars observed show the anterior adductor impressions. The vascular trunks of the dorsal valve diverge from the central line about the center of the shell, after passing around the adductor muscle impressions.

Observations.—The average size of the typical specimens from Texas is from 10 to 14 mm. in length for the ventral valve, the width being about the same. At one locality on Morgans Creek several dorsal valves were found that have a width of 18 mm., with a length of 12 mm. This may possibly indicate a variety or distinct species, but with the material in the collection it is impossible to determine definitely. The shells from the upper Mississippi Valley in Wisconsin and Minnesota average about the same size as the typical forms from Texas. The young shells are much more convex. The material from the Gallatin Range, Yellowstone National Park, is also much like that from Texas, but that from the limestone near Malade, Idaho, though it contains typical shells, also has specimens as large as those from Morgans Creek, Texas.

Billingsella major differs from *B. coloradoensis* in the character of the surface striation, also in its larger size. *Billingsella plicatella* is a uniformly smaller and more convex shell, and also has distinct surface characters. The same is true of *B. striata*.

FORMATION AND LOCALITY.—Lower Ordovician: (339 [Sardeson, 1896, pp. 95 and 96]) Oneota dolomite, Stillwater, Washington County, Minnesota.

Upper Cambrian: (302q) About 1,000 feet (305 m.) above the quartzitic sandstones in the "Yogo limestone (Devono-Silurian)" of W. H. Emmons [1907, p. 34], on Rock Creek, Phillipsburg quadrangle (U. S. Geol. Survey), Granite County; (302r) same horizon as Locality 302q, near Princeton, Phillipsburg quadrangle (U. S. Geol. Survey), Granite County; (302f) limestone in upper part of the Gallatin formation, north side of Elk Pass, between Buffalo and Slough Creeks, Yellowstone National Park, Livingston quadrangle (U. S. Geol. Survey); (147a) limestone in Spring Hill Canyon, west side of the Bridger Range, Gallatin County; and (155) limestone north of East Gallatin River, near Hillsdale, Threeforks quadrangle (U. S. Geol. Survey), Gallatin County; all in Montana.

(302p) Middle limestone of the Deadwood formation near the summit of the Owl Creek Mountains, 18 miles (29 km.) southwest of Thermopolis, Fremont County; (302g) limestone on the north slope of Crowfoot Ridge south of the

Gallatin Valley, Gallatin quadrangle (U. S. Geol. Survey), Yellowstone National Park; and (302h) limestone on the divide between Panther Creek and West Gallatin (Gallatin) River, Gallatin quadrangle (U. S. Geol. Survey), Yellowstone National Park; all in Wyoming.

(4y, 5a, 5c, and 54t) Limestones about 250 feet (76 m.) above the Middle Cambrian; (54x) limestone about 200 feet (61 m.) above the Middle Cambrian; and (54u) limestone about 100 feet (30.5 m.) above the Middle Cambrian; all in the St. Charles formation [Walcott, 1908a, p. 6], on the north side of Twomile Canyon, near its mouth, 2 miles (3.2 km.) southeast of Malade, Oneida County, Idaho.

(56g) Limestones of the St. Charles formation [Walcott, 1908a, p. 6], in the valley of the stream which flows into Mill Canyon from the west, about 6 miles (9.6 km.) west-southwest of Liberty, and 15 miles (24.2 km.) west of Montpelier, Bear Lake County, Idaho.

(54e) About 200 feet (61 m.) above the Middle Cambrian and 1,025 feet (312.4 m.) below the top of the Upper Cambrian, in limestones forming 3 of the St. Charles formation [Walcott, 1908f, p. 193]; (31m and 55h) about 175 feet (53.3 m.) above the Middle Cambrian and 1,050 feet (320 m.) below the top of the Upper Cambrian, near the base of the limestones forming 3 of the St. Charles formation [Walcott, 1908f, p. 192]; and (54f) 150 feet (45.7 m.) above the Middle Cambrian and 1,075 feet (327.7 m.) below the top of the Upper Cambrian in the light-gray sandstone forming 4 of the St. Charles formation [Walcott, 1908f, p. 193]; all in Blacksmith Fork Canyon, about 10 miles (16.1 km.) east of Hyrum, Cache County, Utah.

(14b) Limestone on Cold Creek at north end of gorge opposite the north end of Sponge Mountain, 2 miles (3.2 km.) south of the San Saba County line, in Llano County; (14g) limestone 1 mile (1.6 km.) west of Cherokee, San Saba County; (68 and 68e) interbedded sandstone and limestone, Packsaddle Mountain, Llano County; (69) limestone near Honey Creek, Burnet County; (70, 70a, and 70e) limestones near Morgans Creek, Burnet County; (353a [Shumard, 1860, p. 627]) sandstones near the head of Morgans Creek, Burnet County; and (71) limestone in Cold Creek Canyon, Burnet County; all in Texas.

(369e) Sandstone on Big River, Iron County; (369d) upper portion of the Elvins formation, 2.5 to 3 miles (4 to 4.8 km.) north of Caledonia, Washington County; (111) arenaceous limestone of the Elvins formation, 50 feet (15.2 m.) above the "Edgewise beds," St. Francois County; and (11d) arenaceous limestone about 2 miles (3.2 km.) north of Montana, in sec. 22, T. 35 N., R. 1 E., Iron County; all in Missouri.

"St. Croix sandstone" at the following localities: (78) Quarry near St. Croix River in suburbs of Osceola, Polk County; (79) bluff near Hudson, St. Croix County; (79a) quarry and ledge 0.5 mile (0.8 km.) southeast of the county courthouse, Menomonie, Dunn County; (100) near Menomonie, Dunn County; (80a) 4 miles (6.4 km.) north of Reedsburg, Sauk County; (83') uppermost horizon near Trempealeau, Trempealeau County; (97a) near Winfield, Jefferson County; (328c) at Alma, Buffalo County; and (328d [Whitfield, 1882, p. 171]) at Berlin, Green Lake County; all in Wisconsin.

(83³) Green-sand horizon in the "St. Croix sandstone" below the "fifth trilobite bed" of Owen, at Trempealeau, Trempealeau County, Wisconsin.

"St. Croix sandstone" at the following localities: (84a) River Junction, Houston County, 20 miles (32.2 km.) below Dresbach; (97b) below the green-sand bed and about 25 feet above St. Croix River, at Franconia, Chisago County; (86a) near Red Wing, Goodhue County; (97 and 897x) at Reads Landing, foot of Lake Pepin, Wabasha County; (131) in a cut on the Chicago, Milwaukee and St. Paul Railway, 4 miles (6.4 km.) southeast of Lake City, Wabasha County; (339f) near Minneiska (Miniska), on Mississippi River near the line between Wabasha and Winona counties; (339h [Hall, 1863, p. 135]) near the mouth of Minneiska (Miniska) River, near the line between Wabasha and Winona counties; (98a) at Marine Mills, on St. Croix River, Washington County; and (339g) just below the *Dicellocephalus minnesotensis* beds, near Winona, Winona County; all in Minnesota.

Upper? Cambrian: (306) Sandy limestone on Gravel River, on the eastern slope of the Rocky Mountains, in the Mackenzie Basin, British Columbia.

Middle Cambrian: (5k) Limestone in Meagher County on the road to Wolsey, about 1 mile (1.6 km.) south of the divide at the head of Sawmill Creek, and 8 miles (12.8 km.) south of Neihart, Little Belt Mountains quadrangle (U. S. Geol. Survey), Cascade County; (302w) limestone at Madison Mountain; and (159) limestones north of West Gallatin (Gallatin) River, Gallatin County; all in Montana.

(4e) Limestones about 950 feet (289.6 m.) above the unconformable base of the Cambrian in the divide at the head of Jackson Creek (locally known as Sheep Creek), a creek flowing into Jackson Lake about 0.5 mile (0.8 km.) south of its northwestern corner, Teton Mountains, Grand Teton quadrangle (U. S. Geol. Survey), Uinta County, Wyoming.

(5b and 54s) Dark blue-gray Langston limestone [Walcott, 1908f, p. 198], just above the Cambrian quartzitic sandstones, north side of Twomile Canyon, near its mouth, 2 miles (3.2 km.) southeast of Malade, Oneida County, Idaho.

(54o) About 900 feet (274.3 m.) above the Brigham quartzite and 3,300 feet (1,005.8 m.) below the Upper Cambrian, in the limestone forming 1b of the Ute limestone [Walcott, 1908f, p. 196], in Blacksmith Fork Canyon, about 10 miles (16.1 km.) east of Hyrum, Cache County, Utah.

(11e) Thin-bedded limestones south-southwest of Potosi, Washington County, Missouri.

(2s) Limestone in upper part of *Paradoxides* zone, Hastings Cove [Matthew, 1898b, p. 38], on Kennebecasis Bay, 0.5 mile (0.8 km.) northeast of Torryburn on the Intercolonial Railway northeast of St. John, St. John County, New Brunswick.

BILLINGSSELLA DICE Walcott.

Plate CI, figures 8, 8a-d.

Billingsella dice WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 234. (Characterized essentially as below as a new species.)

In general form and surface this shell is related to *B. romingeri* (Barrande). It differs from the latter in its strong dental plates, which form a rudimentary spondylium. All the characters known are illustrated.

FORMATION AND LOCALITY.—Lower Ordovician?: (319f) Drift bowlder of sandstone found near St. Albans, Franklin County, Vermont. The lithologic character of the matrix in which this species was found points to the arenaceous limestones of the Phillipsburg formation just north of the boundary between the United States and Canada as the source of the bowlder.

BILLINGSSELLA EXPORRECTA (Linnarsson).

Plate LXXXVIII, figures 1, 1a-1.

Orthis exporrecta LINNARSSON, 1876, Bihang till K. svensk. Vet.-Akad. Handl., Bd. 3, No. 12, pp. 12-13, Pl. II, figs. 13-19; Pl. III, figs. 20 and 21. (Described and discussed in English as a new species.)

Orthis exporrecta LINNARSSON, KAYSER, 1883, China, by Richthofen, vol. 4, p. 35. (Discussed in German in the description of "*O. linnarssoni*.")

Orthis exporrecta LINNARSSON, WALLERIUS, 1895, Undersökningar öfver Zonen med *Agnostus levigatus* i Vestergötland, p. 66. (Localities mentioned in Swedish.)

Billingsella exporrecta (Linnarsson), WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 234-236. (Described and discussed essentially as below.)

Shell transversely subsemicircular, with the hinge line usually shorter than the greatest width. In a few examples it is a trifle longer; the cardinal angles are obtusely angular (Pl. LXXXVIII, fig. 1e). The proportions between the length and breadth vary, as shown by the figures. The ventral valve is considerably more convex than the dorsal. The ventral valve is evenly rounded, while the dorsal usually has a flattening of the median area and sometimes a slight, broad sinus. The surface is marked by numerous radiating costæ and very fine concentric striæ between the costæ, and a few visible lines of growth. The costæ are rounded, usually, but not always, broader than the interspaces, and continuous from the umbo to the front and lateral margins; they appear to be quite regular, although varying much in size, and increasing somewhat irregularly by interpolation of new costæ. This usually occurs near the umbo, but may occur near the middle of the valve. The largest ventral valve in the collection has a length of 9 mm. and a breadth of 11 mm. Dorsal valve: Length, 7 mm.; breadth, 10 mm.

Cardinal area of ventral valve high and overhanging the posterior margin. Delthyrium large and triangular in outline; deltidium short, concave, imperforate, and marked by fine, transverse striæ of growth. Cardinal area of dorsal valve short and inclined slightly forward; it is divided midway by a broad delthyrium, which is divided by a strong cardinal process.

In the interior of the ventral valve strong main vascular sinuses extend well forward toward the front margin. The cast of the umbonal cavity opposite the delthyrium shows a tripartite division, the center of which is the area of the path of advance of the diductor muscle impressions, and those on each side appear to be the posterior portion of the main vascular sinuses. The anterior edge of the cavity is marked by a sharp, elevated, forward-arching ridge that extends to the teeth on either side; the dental plates appear to have extended to the bottom of the valve and to have bounded the sides of the triangular umbonal cavity opposite the delthyrium.

The interiors of the dorsal valve are beautifully preserved. The cardinal process, crura, crural plates, area, anterior and posterior adductor muscle scars, and vascular sinuses are very distinct; the dental sockets are shallow, but clearly shown. The great variation in the size, form, and position of the adductor scars is well illustrated by the figures. In figure 1f there appear to be two lateral supporting septa to the thickening before the crural plates that

bound the spaces occupied by the point of attachment of the diductor muscles. Linnarsson describes [1876, p. 12] the cardinal process as triangular. I find it both straight (fig. 1f), subtriangular (fig. 1i), and triangular (figs. 1g and 1h). A short median septum is seen in some shells (fig. 1g), but usually the strong, slightly rounded, flattened median ridge does not carry it.

Observations.—This is one of the most variable species of the genus, both in external, and, as far as known, internal characters. It is very abundant, but interiors of the ventral valve are rarely met with in good condition.

The extremely short, imperforate deltidium of the ventral valve indicates that the pedicle opening had been closed by shell growth, and that this species was nearing the *Eoorthis rem-nicha* stage of development. It appears to be an intermediate form between *Billingsella* and *Eoorthis*. The concave deltidium is much like that of *Conchidium nysius* Hall and Whitfield [Hall and Clarke, 1894, Pl. LXIV, fig. 7]. It is about one-fifth the length of the delthyrium.

Linnarsson [1876, p. 12] compares "*Orthis exporrecta*" with "*Orthis hicksi*," which appeared to be most nearly related, pointing out that it differed in having fewer and coarser ribs, less pointed beak, and lower area. The "*Orthis hicksi*" variety is now placed as a variety of *Billingsella exporrecta*.

FORMATION AND LOCALITY.—**Upper? Cambrian:** (310h) Shale collected somewhere (probably Fogelsång) in the old province of Skåne, Sweden.

Middle Cambrian: Limestones of the *Paradoxides forchhammeri* zone at the following localities: (320m)^a at Kinnekulle, northeast of Lidköping, Province of Skaraborg; (320n) at Lovened, Djupadal, 19 miles (30.6 km.) south-southeast of Skara, Province of Skaraborg; (320y)^a at Gudhem, 12.5 miles (20.1 km.) south-southeast of Skara, Province of Skaraborg; (320p)^a at Södra Möckleby, southern part of Oeland Island; (320z)^a several places in Nerike; (320g) at Borgholm, Oeland Island; (321q) at Munkesten, north of Hunneberg; and (321r) at Hunneberg, western boundary of the Province of Skaraborg; all in Sweden.

(3201)^a Drift blocks supposed to have come from the *Paradoxides wlandicus* zone [Linnarsson, 1876, p. 6], at Lillviken, near Oestersund, Province of Jemtland; (321p [Wallerius, 1895, p. 67]) in strata with *Agnostus lævigatus* at Carlfors, near the north end of Mount Billingen, Province of Wermland; (310z) at Brantevik, on the shore a little south of Simrishamn, Province of Christianstad; (320b) limestones forming 2d of the *Paradoxides* zone, the *Agnostus lævigatus* horizon, at Gudhem, 12.5 miles (20.1 km.) south-southeast of Skara, Province of Skaraborg; and (310b) dark-brown limestone at Borgholm, Oeland Island; all in Sweden.

BILLINGSSELLA EXPORRECTA RUGOSICOSTATA Walcott.

Plate LXXXVIII, figures 2, 2a-c.

Orthis hicksi LINNARSSON [not SALTER MS., DAVIDSON]. 1876, Bihang till K. svensk. Vet.-Acad. Handl., Bd. 3, No. 12, pp. 13-14, Pl. III, figs. 22 and 23. (Described and discussed in English.)

Billingsella exporrecta rugosicostata WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 236. (Discussed as below as a new variety.)

Linnarsson [1876, p. 13] recognized that this shell was not the same as his "*Orthis exporrecta*" and placed it provisionally under *Orthis hicksi*, calling attention to the fact that it was nearly related to *O. exporrecta*. With a fine series of specimens for comparison, I place the shell as a variety of *B. exporrecta*. It is characterized by its strong, irregular costæ. Linnarsson [1876, p. 14] gives as the most important differences: "Ventral valve less convex; cast of diductor muscle scars less distinct; dorsal valve more convex and muscle scars more strongly marked; radiating ribs in the casts fewer, stronger, and more angular." All of the differences exist when we compare the extreme forms, but with a good series of specimens most of them pass gradually into forms that are typical of *B. exporrecta*.

FORMATION AND LOCALITY.—**Middle Cambrian:** Limestones of the *Paradoxides forchhammeri* zone at the following localities [Linnarsson, 1876, p. 14]: (320m) At Kinnekulle, northeast of Lidköping, Province of Skaraborg; (320n) at Lovened, Djupadal, 19 miles (30.6 km.) south-southeast of Skara, Province of Skaraborg; and (320p) at Södra Möckleby, southern part of Oeland Island; all in Sweden.

(320b) Limestone forming 2d of the *Paradoxides* zone, the *Agnostus lævigatus* horizon, at Gudhem, 12.5 miles (20.1 km.) south-southeast of Skara, Province of Skaraborg, Sweden.

BILLINGSSELLA HICKSI (Salter MS.) (Davidson).

Plate XCVII, figures 7, 7a-b.

Orthis hicksii (SALTER MS.) DAVIDSON, 1868, Geol. Mag., vol. 5, p. 314, Pl. XVI, figs. 17-19. (Described as a new species; see below for copy.)

Orthis hicksii DAVIDSON, 1869, British Fossil Brachiopoda, vol. 3, pt. 7, No. 3, p. 230, Pl. XXXIII, figs. 13-16. (Described. Figs. 13a and 14a are copied from Davidson, 1868, Pl. XVI, figs. 17a and 18a. Fig. 16a is an enlarged drawing of the specimen figured by Davidson, 1868, Pl. XVI, fig. 19. Figs. 14a, 13a, and 16a are copied in this monograph, Pl. XCVII, figs. 7, 7a-b, respectively.)

Orthis hicksi DAVIDSON, KAYSER, 1883, China, by Richthofen, vol. 4, p. 35. (Discussed in German in the description of "*O. linnarssoni*."

Billingsella hicksi (Davidson), WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 237. (Original description, Davidson, 1868, p. 314, copied as below.)

The original description by Davidson follows:

Shell small, transversely oval; hinge line shorter than the greatest breadth of the shell; cardinal angles rounded. Dorsal valve semicircular, moderately convex, slightly longitudinally depressed along the middle. Ventral valve convex, deeper than the opposite one. Area triangular, moderately wide; surface of valves ornamented by about ten principal narrow, radiating ribs, with wide interspaces between each pair, in the middle of which is situated a shorter rib.

Length about 4, width 5, lines.

This shell is most nearly related to *B. exporrecta*. It differs in its more rounded form, fewer radiating ribs, and muscle area of ventral valve.

The specific name was given in honor of Henry Hicks.

FORMATION AND LOCALITY.^a—Middle Cambrian: Sandstones in the middle portion of the Menevian at the following localities [Davidson, 1869, p. 230]: (318d) at Porth-y-rhaw; (318h) at St. Davids; and (318p) at Ninewells; all near St. Davids, South Wales.

BILLINGSSELLA HIGHLANDENSIS (Walcott).

Plate LXXXVII, figures 4, 4a-c.

Orthis? highlandensis WALCOTT, 1886, Bull. U. S. Geol. Survey No. 30, pp. 119-120, Pl. VIII, figs. 3, 3a-b. (Described and discussed as a new species. The specimens represented by figs. 3, 3a-b are redrawn in this monograph, Pl. LXXXVII, figs. 4c, 4b, and 4, respectively.)

Orthis? highlandensis WALCOTT, 1891, Tenth Ann. Rept. U. S. Geol. Survey, p. 612, Pl. LXXII, figs. 5, 5a-b. (Mentioned. The figures are copied from those in the preceding reference.)

Billingsella highlandensis WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 237-238. (Described and discussed essentially as below.)

Shell transversely oval or subrotund. Front broadly rounded and nearly straight in the dorsal valve. On the ventral valve the cardinal line slopes toward the beak at an angle of about 20°, while in the dorsal valve it is less than 10°. The greatest width is about the middle of the shell. The ventral valve is moderately convex, being most elevated toward the beak, which is slightly arched over to the cardinal margin.

A dorsal valve associated in the same hand specimen of limestone is more convex than the ventral valve. The cardinal line is shorter than the greatest width of the shell. The median fold is but slightly raised above the general surface, although the front margin has a low, broad arch for the reception of the fold of the ventral valve.

A slight flattening in the central portion of the ventral valve in some specimens forms a low, broad mesial sinus toward the front margin.

The surface is marked by concentric lines of growth and fine radiating ribs; on some specimens stronger ribs occur very much as on *Billingsella coloradoensis* (Pl. LXXXV, figs. 1a-i). Interior casts of the valves show fine, radiating striae toward the front. In a number of partly exfoliated shells, the shell is shown to be thick and apparently solid, having been replaced by calcite.

The average-sized ventral valve has a length of 13 mm., with a width of 16 mm. One dorsal valve is 17 mm. in width.

^a Specimens from localities 318h and 318p are included in the collections of the United States National Museum. The type locality is either 318d or 318p, Davidson does not indicate which.

Cardinal area of the ventral valve unknown except that its plane extends backward at an angle of about 10° or 15° to the plane of the margin of the shell.

Casts of the interior of the ventral valve show that the dental plates extend down to the bottom of the valve, supporting distinctly defined hinge teeth. The traces of a vascular system are limited to the main vascular trunks, which extend forward well toward the front margin, very much as in *B. coloradoensis*. In one cast (Pl. LXXXVII, fig. 4b) there is a strong furrow extending from a median furrow obliquely outward to each main vascular sinus. The median furrow extends backward to the apex of the cast that filled the space beneath the umbo and the deltidium. This portion of the cast is also marked by fine vertical venation. In another cast there is a very narrow median furrow. These median furrows probably indicate the beginning of a septum that in later forms connected the deltidium with the shell. Nothing is known of the interior of the dorsal valve.

Observations.—*Billingsella highlandensis* is strongly characterized by its nearly smooth surface, in having the dorsal valve more convex than the ventral, and in the presence in the ventral valve of a sharp ridge beneath the umbo, indicating the beginning of the growth of a median septum.

The specific name is derived from the Highland Range, Nevada.

FORMATION AND LOCALITY.—**Lower Cambrian:** (30) Limestone 8 miles (12.8 km.) north of Bennetts Spring, on the west slope of the Highland Range; and (31a) limestones and interbedded siliceous shales in the Pioche formation [Walcott, 1908a, p. 11], just above the quartzite on the east side of the anticline, near Pioche; both in Lincoln County, Nevada.

This species is somewhat doubtfully identified from the following locality:

Lower Cambrian: (178a) Sandstone at the south end of Deep Spring Valley, Inyo County, California.

BILLINGSSELLA LINDSTRÖMI (Linnarsson).

Plate LXXXVII, figures 6, 6a-f.

Orthis lindströmi LINNARSSON, 1876, Bihang till K. svensk. Vet.-Akad. Handl., Bd. 3, No. 12, pp. 10-12, Pl. I, figs. 1-8; Pl. II, figs. 9-12. (Described and discussed in English as a new species.)

Billingsella lindstromi WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 238-239. (Characterized and discussed as below.)

The general description of *Billingsella coloradoensis* applies to this species. The casts of the interior have the same general flatness of appearance, and the exterior surfaces are not unlike. In details, the two differ materially. The radiating costæ of *B. lindströmi* are usually stronger; the umbo of the ventral valve is more prominent and the beak more incurved. The interior of the ventral valve shows shorter main vascular sinuses and more limited ovarian areas.

Linnarsson [1876, Pl. I] gives a fine series of illustrations of the interior of the ventral valve, which show that there is considerable variation in the position of the vascular markings. He states that the small cardinal process appears to be bifid. I find it single in a natural cast in the limestone from Alunbruk. There is also a narrow median septum, as in the dorsal valve of *B. coloradoensis*.

Linnarsson [1876, p. 11] writes:

I do not know any species with which this can be confounded. At least, the adult specimens are always easily recognized. In the young ones the characters are less marked, especially in the dorsal valves. The interior and the internal cast of the ventral valve is in all stages of growth easily recognized.

The specific name was given in honor of Dr. G. Lindström.

FORMATION AND LOCALITY.—**Middle Cambrian:** Limestones of the *Paradoxides forchhammeri* zone at the following localities: (320m)^a At Kinnkulle, northeast of Lidköping, Province of Skaraborg; (320n)^a at Lovened, Djupadal, 19 miles (30.6 km.) south-southeast of Skara, Province of Skaraborg; (320y)^a at Gudhem, 12.5 miles (20.1 km.) south-southeast of Skara, Province of Skaraborg; and (320p) at Södra Möckleby, southern part of Oeland Island; all [Linnarsson, 1876, p. 12] in Sweden.

(3201) [Linnarsson, 1876, p. 12] Drift blocks supposed to have come from the *Paradoxides alandicus* zone, at Lillviken, near Oestersund, Province of Jemtland; (320q)^a limestone at Alunbruk (alum works), southern part of Oeland Island; (321t) sandstone at Sularp, near Lund, Province of Malmöhus; and (321u) at Bjorkelunda, south of Simrishamn, Province of Christianstad; all in Sweden.

^a These localities are represented in the collections of the United States National Museum.

BILLINGSSELLA MAJOR Waleott.

Plate LXXXVI, figures 1, 1a.

Billingsella major WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 239. (Characterized as below as a new species.)*Billingsella major* WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 3, p. 101, Pl. X, figs. 1 and 1a. (Characterized as in the preceding and as below as a new species. Figs. 1 and 1a are copied in this monograph, Pl. LXXXVI, figs. 1 and 1a, respectively.)

In general form and convexity this shell is related to *Billingsella coloradoensis*. It differs from it in being larger and in having coarser radiating ribs. It is the Upper Cambrian representative of the latter species.

FORMATION AND LOCALITY.—Upper Cambrian: (116) "St. Croix sandstone" in excavation on Well's farm, 2 miles (3.2 km.) west of Baraboo, Baraboo quadrangle (U. S. Geol. Survey), Sauk County, Wisconsin.

Specimens that are somewhat doubtfully referred to this species occur at the following locality:

Upper Cambrian: (369c) Dolomite above the "Edgewise beds," in a railroad cut, 0.5 mile (0.8 km.) southwest of Elvins, 6 miles (9.6 km.) south of Bonnetterre, St. Francois County, Missouri.

BILLINGSSELLA MARION Waleott.

Text figures 67A–B.

Billingsella marion WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 3, p. 102, Pl. X, fig. 5. (Described and discussed as below as a new species. Fig. 5 is copied in this monograph as fig. 67A.)

Dorsal valve transverse; beak small, marginal; sides broadly rounded and merging into the broadly round, almost transverse frontal margin; cardinal line a little shorter than the greatest width of the valve and sloping very slightly from the beak to outer extremities; on one specimen the cardinal angle is extended slightly; greatest width about midway of the length; mesial furrow narrow at the beak and gradually widening to a broad, deep furrow, which divides the valve into two lobes.

FIGURE 67.—*Billingsella marion* Waleott. A, Dorsal valve, the type specimen, showing extension of the cardinal angle and a very broad mesial furrow. B, Dorsal valve with obscure radiating ribs.

The specimens represented are from Locality 581, Middle Cambrian on Mount Stephen, British Columbia (U. S. Nat. Mus. Cat. Nos. 53676a and 53676b, respectively). Figure 67A is copied from Waleott [1908d, Pl. X, fig. 5].

Surface smooth, with the exception of a few (six or seven) obscure radiating ribs on each lobe. A specimen 10 mm. in width has a length of 6 mm.

Observations.—This species is represented by three specimens of the dorsal valve. They all indicate a thick shell of the *Billingsella salemensis*

(Waleott) type (Pl. LXXXVII, figs. 3 and 3a).

The specific name was given for Mrs. L. D. Burling, who collected the type specimen.

FORMATION AND LOCALITY.—Middle Cambrian: (581) About 1,830 feet (557.8 m.) above the Lower Cambrian in limestones forming 3b of the Stephen formation [Waleott, 1908c, p. 238 (7)], on the east side of Mount Stephen, about 3,000 feet (914.4 m.) above the Canadian Pacific Railway track, 3.5 miles (5.6 km.) east of Field, British Columbia, Canada.

BILLINGSSELLA OBSCURA Waleott.

Plate LXXXVI, figure 6.

Billingsella obscura WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 239. (Characterized as below as a new species.)

This species is founded on a single dorsal valve that occurs in the form of a cast in sandstone. It is transverse, width 18 mm., length 13 mm.; moderately convex, with a slightly defined mesial flattening that broadens out nearly to three-fifths the width of the shell at the front margin. The surface of the cast is marked by a few faintly defined, rather broad costae.

The shell is much like the large dorsal valves of *Billingsella coloradoensis*. It differs in its broader frontal margin and median flattening.

FORMATION AND LOCALITY.—Middle Cambrian: (74) Sandstone about 300 feet (91.4 m.) above the base of the Tonto group at the head of Nunkoweap Valley, Grand Canyon of the Colorado, Arizona.

BILLINGSSELLA ORIENTALIS (Whitfield).

Plate LXXXVI, figures 2, 2a-b.

Orthisina orientalis WHITFIELD, 1884, Bull. Am. Mus. Nat. Hist., vol. 1, p. 144, Pl. XIV, fig. 6. (Described and discussed as a new species. Fig. 6 is copied in this monograph, Pl. LXXXVI, fig. 2.)

Orthisina orientalis Whitfield, WALCOTT, 1886, Bull. U. S. Geol. Survey No. 30, p. 120, Pl. VII, fig. 6. (Original description, Whitfield, 1884, p. 144, copied and species discussed. Fig. 6 is copied from fig. 6 of the preceding reference.)

Orthisina orientalis Whitfield, WALCOTT, 1891, Tenth Ann. Rept. U. S. Geol. Survey, p. 613, Pl. LXXII, fig. 8. (Mentioned. Fig. 8 is copied from Whitfield, 1884, Pl. XIV, fig. 6.)

Billingsella orientalis (Whitfield), HALL and CLARKE, 1892, Nat. Hist. New York, Paleontology, vol. 8, pt. 1, p. 230. (Merely changes generic reference.)

Billingsella orientalis (Whitfield), WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 239-240. (Described and discussed as below.)

The original description by Whitfield follows:

Shell quadrangular in outline, somewhat higher than wide, with vertical and subparallel lateral margins, and broadly rounded base. Cardinal line rapidly sloping from the apex to the extremities, which are slightly rounded. Hinge line straight, as long as the greatest width of the shell. Cardinal area broad and high, divided in the middle by a triangular foramen, which is about as high as wide. Surface of the ventral valve moderately convex, marked by very fine radiating striæ and also by several concentric lines of growth. Filling of the rostral cavity and foramen large and prominent. Specimen, a cast in shale, of the ventral valve only.

Observations.—The type specimen as described above is flattened in the shale, and also appears to be compressed laterally. Uncompressed specimens referred to this species, from the siliceous limestones east of Swanton show the ventral valve to have been rather strongly convex, and the dorsal valve moderately so. The outer surface as shown in the cast indicates that it was somewhat like that of *Billingsella coloradoensis*, but that it differs in having finer and more numerous threadlike costæ. A few traces of concentric striæ and lines of growth are preserved. The material is very unsatisfactory, but it is sufficient to indicate that the genus occurs in association with *Olenellus thompsoni* in the upper beds of the Lower Cambrian section.

FORMATION AND LOCALITY.—Lower Cambrian: (25a) Limestone on the Hall (Donaldson's) farm, 2 miles (3.2 km.) east of Swanton; (26) sandstone northeast of the Corman farm buildings, east of Highgate Springs; (319m) shales of No. 6 of the section at Parker's quarry [Walcott, 1891b, p. 278], near Georgia; and (319g [Whitfield, 1884, p. 144]) shales at Parker's quarry, near Georgia; all in Franklin County, Vermont.

BILLINGSSELLA PLICATELLA Walcott.

Text figure 1, page 299; Plate LXXXVI, figures 3, 3a-n.

Billingsella plicatella WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 240-241. (Described and discussed as below as a new species.)

Shell irregularly subquadrate in outline. In the ventral valve the cardinal line slopes toward the beak at an angle of from 5° to 10°, whereas in the dorsal valve it is usually about 1° to 3°. The greatest width of the shell is about the middle. There is some variation in the relative proportions of length and breadth. Usually, however, the ventral valve is fully as long as wide, while in the dorsal valve it is slightly transverse. The ventral valve is rather strongly convex, the dorsal valve being less so. A low, broad mesial sinus occurs on nearly all specimens of the dorsal valve, and sometimes a distinct sinus on the ventral valve.

The surface is marked by costæ that give it a plicated appearance in many specimens; also, concentric lines of growth and very fine, slightly undulating striæ. On some shells the costæ and surface markings have been almost entirely removed by abrasion while in others they are clear and distinct. There is a considerable range of variation in the strength and form of the surface markings. These are illustrated by the figures on Plate LXXXVI.

When the shell is exfoliated, fine radiating lines occur toward the front margins. The average size of the shell gives a width of about 8 mm., and in the ventral valve a nearly equal length. One specimen has a width of 11 mm.

Cardinal area well defined. It is marked by transverse striæ of growth parallel to the base. The plane of the area extends backward over the cardinal line at an angle of 10° to the plane of the margin of the shell. The delthyrium is well defined and covered by a convex deltidium, the extent of which, however, is unknown. The cardinal area of the dorsal valve is short. No details of the structure have been observed.

The cast of the interior of the ventral valve indicates short hinge teeth supported by dental plates. The markings left on the shell by the vascular system, as shown in casts, are two main vascular trunks which extend nearly in a straight line from the side of the cast of the deltidial cavity obliquely outward to the anterior fourth of the valve, where they bifurcate. The inner branch extends in toward the median line, while the lateral branches extend outward, appearing to unite with the peripheral canal. The latter arches about the space that was probably occupied by the ovarian areas, between itself and the main vascular trunks. The spaces for the attachment of the muscles between the main vascular trunks appear to have been large. No subdivision indicating the points of attachment of the different muscles has been detected. At the posterior portion of the central area there was a narrow, elevated space that posteriorly passes into the deltidial cavity. The pedicle muscles were probably attached to the front part of this elevated space. Short, radiating striæ near the margin indicate the presence of minute vascular canals.

In the interior of the dorsal valve the interior of the deltidial cavity supports a small, well-developed cardinal process or callosity. The crura are short and small, with rounded dental sockets beside them. Nothing is definitely shown of the vascular trunks or mesial impressions in the dorsal valve.

Observations.—In form this species is not unlike the convex forms that have been referred to *Billingsella coloradoensis* (Shumard) from Trempealeau, Wisconsin. It differs from the latter in having strongly marked surface plications and a narrower deltidium. From *B. striata* it differs in surface characters; also in having a more convex dorsal valve.

FORMATION AND LOCALITY.—**Upper Cambrian:** (150a, 153, and 154) Limestones on Dry Creek, just above the mouth of Pass Creek, about 5 miles (8 km.) north of Hillsdale; (151a) limestone in point overlooking Churn Canyon on the west side of the Bridger Range; (157 and 158)^a limestone north of East Gallatin River, near Hillsdale; and (156b) limestone north of East Gallatin River, at the north end of the Gallatin Valley; all in the Threeforks quadrangle (U. S. Geol. Survey), Gallatin County, Montana.

(152) Limestone on ridge between Churn and Cottonwood canyons; and (151) limestone in point overlooking Churn Canyon; both on the west side of the Bridger Range, Gallatin County, Montana.

Middle Cambrian: (9h) Limestone on Beaver Creek, 5 miles (8 km.) north of York, about 8 miles (12.8 km.) north of Canon Ferry, Big Belt Mountains, Fort Logan quadrangle (U. S. Geol. Survey), Meagher County, Montana.

(4j) Limestone at the head of Deep Creek, Canyon quadrangle (U. S. Geol. Survey), Yellowstone National Park, Wyoming.

BILLINGSSELLA PUMPELLYI Walcott.

Plate XCVII, figures 8, 8a-c.

Billingsella pumpellyi WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 242. (Described and discussed as below as a new species.)

General outline subsemicircular, greatest width at the hinge line or a little in advance of it; considerable variation exists in the relative proportions of length and width; a ventral valve 8 mm. long has a width of 9 mm.; the dorsal valve is more transverse, length 5.5 mm., width 8 mm. The ventral valve is strongly convex, with the umbo arching over to the apex, which is a little above the plane of the margins of the valve; a very slight median fold occurs near the front margin; dorsal valve slightly convex and with a shallow median sinus.

The surface is marked by low, sharp ribs with wide interspaces on which fine radiating striæ occur. Concentric lines and striæ of growth cross the radiating striæ and ribs.

The characters of the cardinal areas of the valves are almost unknown; that of the ventral valve appears to have been of moderate height and inclined but a little from the plane of the valve; one interior of the dorsal valve shows a low cardinal process. The cast of the interior

^a158 is the type locality.

of the ventral valve shows the presence of a tripartite, elevated umbonal space into which the strong main vascular sinuses extend, as in *Billingsella coloradoensis* (Shumard); the sinuses extend forward nearly to the front margin of the valve. Of the interior of the dorsal valve only the presence of a strong median ridge is known.

Observations.—This species is one of the costate species of the type of *Billingsella coloradoensis* (Shumard) and *B. romingeri* (Barrande). It differs from them in surface characters. It may be considered the trans-Pacific representative of *B. coloradoensis*.

The specific name was given in honor of Raphael Pumpelly.

FORMATION AND LOCALITY.—Upper Cambrian: (C36) Upper part of the Chaumitien limestone [Blackwelder, 1907a, p. 36 (part of 3d list of fossils), and fig. 9 (bed 2), p. 35], at Chaumitien, Changhia district; and (C61) a dense black limestone in the uppermost limestone member of the Kiulung group [Blackwelder, 1907a, pp. 37 and 41 (3d list of fossils) and fig. 10 (bed 13), p. 38], 3 miles (4.8 km.) southwest of Yenchuang; both in Shantung, China.

BILLINGSSELLA RETROFLEXA (Matthew).

Plate XC, figures 1, 1a-h.

Not *Gonambonites plana retroflexa* DE VERNEUIL [PANDER, 1830, Beiträge zur Geognosie des russischen Reiches, p. 77, Pl. XXV, figs. 1 and 2].

Clitambonites (Gonambonites) plana retroflexa MATTHEW, 1895, Trans. Roy. Soc. Canada for 1895, 2d ser., vol. 1, sec. 4, No. 13, p. 267, Pl. II, figs. 1a-c. (Original description of *Gonambonites plana retroflexa* by de Verneuil [Pander, 1830, p. 77] copied and variety from Cape Breton described and discussed. The specimens represented by figures 1a and 1b are redrawn in this monograph, Pl. XC, figs. 1g and 1f, respectively.)

Clitambonites planus retroflexus (Matthew), SCHUCHERT, 1897, Bull. U. S. Geol. Survey No. 87, p. 184. (Merely changes generic reference.)

Billingsella retroflexa MATTHEW, 1903, Geol. Survey Canada, Rept. Cambrian Rocks Cape Breton, pp. 148-151, Pl. X, figs. 2a-e. (Described and discussed. Figs. 2a, 2c, and 2e are copied from Matthew, 1895b, Pl. II, figs. 1a-c, respectively. The specimens represented by figs. 2a, 2c, and 2d are redrawn in this monograph, Pl. LX, figs. 1g, 1f, and 1c, respectively.)

Orthis (Plectorthis) retroflexa (Matthew), WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 270-271. (Characterized and discussed essentially as below.)

This species is distinguished by the fine radiating costæ on the ventral valve (Pl. XC, figs. 1, 1a-c) and coarser costæ on the dorsal (fig. 1f). The fine longitudinal striæ on the costæ are shown by figure 1e. The latter are similar to those of *Eoorthis remnicha* (Pl. XCII fig. 2c). All that could be definitely determined of the interior of the valves in the type material sent me by Matthew is shown by figures 1f, 1g, and 1h. In figure 1g of the ventral valve the casts of the pseudospondylium, area, and base of the main vascular sinuses are shown. In figure 1f of the dorsal valve the casts of the strong cardinal process, dental sockets, and crura are shown, and in figure 1h the ovarian areas and the visceral area between them. Matthew [1903, p. 148] describes other features of the interior of the valves.

The character of the costæ and general features of this shell, as far as known, appear to class it with *Billingsella romingeri* (Barrande) (Pl. XC) and *B. coloradoensis* (Shumard) (Pl. LXXXV).

Matthew's very full description [Matthew, 1903, pp. 148-151] should be read by the student of this species. By inadvertence [Walcott, 1905a, p. 270] I referred it to *Orthis (Plectorthis)*, a name which I was then using to include those forms which are now placed under *Eoorthis*.

FORMATION AND LOCALITY.—Middle Cambrian: (307d [Matthew, 1903, p. 149]) Sandy limestone of Matthew's [1903, p. 19] Etcheminian, on Young (McFees) Point, near George River, Cape Breton, Nova Scotia.

BILLINGSSELLA RICHTHOFENI Walcott.

Plate LXXXIX, figure 1.

Billingsella richthofeni WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 242-243. (Characterized and discussed as below as a new species.)

This species is represented by two specimens of the exterior of the ventral valve measuring 4 and 5 mm., respectively, in length and width, these being about the same. The outer surface is marked by fine, obscure, radiating ribs and very fine concentric striæ. The general

form is much like that of the ventral valve of *Billingsella pumpellyi*. It differs from the latter in having a shorter hinge line in proportion to the width, in the more uniform and stronger convexity of the surface, and in the more elevated apex.

The species is named after Dr. Ferdinand von Richthofen.

FORMATION AND LOCALITY.—**Lower Cambrian:** (C3) Lower part of the Manto shale [Blackwelder, 1907a, p. 28 (list of fossils at bottom of page), and fig. 8a (bed 20), p. 28] 2.5 miles (4 km.) southwest of Yenchuang, Sintai district, Shantung, China.

A single specimen of a fragmentary ventral valve that may belong to this species occurs in the following locality:

Lower Cambrian: (C20) Central part of the Manto shale [Blackwelder, 1907a, p. 26 (last list of fossils), and fig. 6 (bed 14), p. 25] on the west side of an isolated butte 1 mile (1.6 km.) south of Changhia, Shantung, China.

BILLINGSSELLA ROMINGERI (Barrande).

Plate XC, figures 2, 2a-n.

Orthis romingeri BARRANDE, 1848, Naturw. Abhandl., von Haidinger, Bd. 2, Abth. 1, No. 5, p. 203, Pl. XVIII, figs. 5a-d. (Described and discussed in German as a new species.)

Orthis romingeri BARRANDE, 1879, Système silurien du centre de la Bohême, vol. 5, pt. 1, Pl. LXII, figs. 11: 1-4. (Figs. 3a, 3c, 3b, 3d, and 3e are copied in this monograph, Pl. XC, figs. 2, 2a-d, respectively.)

Orthis romingeri Barrande, POMPECKI, 1896, Jahrb. K.-k. geol. Reichsanstalt, Bd. 45, Hft. 3, pp. 513-514, Pl. XV, figs. 1-5a. (Described and discussed in German.)

Billingsella romingeri (Barrande), WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 243-244. (Described and discussed as below.)

Shell transverse, the general outline being irregularly subquadrate to subsemicircular. On the ventral valve the cardinal line slopes toward the beak at a low angle, while in the dorsal valve it is approximately straight. In some shells the greatest width is at the hinge line, while in others it is about the middle of the valve. There is considerable variation in length and breadth, as may be seen by comparing the figures illustrating this species.

The ventral valve is rather strongly convex and the dorsal valve moderately so. The dorsal valve is slightly flattened from the umbo to the frontal margin, the flattening sometimes taking the form of a shallow depression. A low, broad mesial sinus occurs on the dorsal valve and is strongly marked in the young shells. The surface is marked by rounded, bifurcating, radiating costæ crossed by concentric lines of growth and undulating concentric striæ. The radiating costæ vary in size and character in specimens from the same locality. In some specimens they are very regular, while in others there will be wider interspaces or a variation in the manner of interpolation. The ridges of growth also vary in strength and elevation in different shells.

The largest shell in a considerable quantity of material has a length in the ventral valve of 13 mm. and in the dorsal valve of 10 mm., with a width of 15 mm. Cardinal area of ventral valve rather high and slightly incurved. It is marked by transverse striæ of growth that cross it parallel to its base; the plane of the area extends backward at an angle of about 10° to the plane of the margin of the shell; the delthyrium is rather large; a deltidium is indicated in some of the casts, but none of the specimens show it clearly. The cardinal area of the dorsal valve is about one-half the length of that of the ventral valve; it extends backward at an angle of more than 45° to the plane of the margin of the valve and is divided midway by a strong delthyrium which is covered, for a part of its distance at least, by a convex chlidium.

The traces of the vascular system in the ventral valves are seen in the main vascular trunks, which extend well forward toward the front margin, where they appear to bifurcate, the inner branch extending toward the median line and the lateral branches apparently connecting with the peripheral canal that arches backward about the ovarian areas between it and the main vascular trunks. No points of attachment of the various muscles in the ventral valve have been observed. The area in which the diductor muscles are attached is well marked in Plate XC, figures 2h and 2i, and the cardinal process of the dorsal valve in figures 2j and 2k. There

are also in the dorsal valve the anterior adductor impressions, as shown in figure 2k. In the interior of the dorsal valve the deltidial cavity separates a small cardinal process or callosity, which is straight (fig. 2l) or subtriangular (fig. 2k). The crura are relatively long and very prominent, with distinctly defined dental sockets beside them.

Observations.—This species was well illustrated by Barrande [1879a, Pl. LXII, fig. 11], and I have copied five of his figures of a specimen showing the two valves united. In the material of the collections of the Museum of Comparative Zoology, Cambridge, Massachusetts, there is a fine series, illustrating the interior of the ventral and dorsal valves, that, through the kindness of Dr. Alexander Agassiz, I was enabled to study and illustrate.

The species in its external and internal shape varies so decidedly from all described forms that it is not necessary to point out differences between them.

The specific name was given in honor of Dr. Carl Rominger.

FORMATION AND LOCALITY.—**Middle Cambrian:** (345 [Pompeckj, 1896b, p. 509])^a Greenish shale in the *Paradoxides* zone, on the Dlouhá Hora, above the brook of Sbirov, near Skrej; (345c)^a in shales of Étage C at Mleschitz; (345f) in Étage C [Barrande, 1879a, Pl. LXII], near Skrej; (345g) in Étage C [Barrande, 1879a, Pl. LXII], at Praschno Augezd; (345l)^a shales of Étage C at Jinec; and (345h) in Étage C [Barrande, 1879a, Pl. LXII], at Slap; all in Bohemia, Austria-Hungary.

BILLINGSSELLA SALEMENSIS (Walcott).

Plate LXXXVII, figures 3, 3a.

Orthis salemensis WALCOTT, 1887, Am. Jour. Sci., 3d ser., vol. 34, pp. 190–191, Pl. I, figs. 17 and 17a. (Described and discussed as below as a new species. The specimens represented by figs. 17 and 17a are redrawn in this monograph, Pl. LXXXVII, figs. 3 and 3a, respectively.)

Orthis salemensis Walcott, OEHLERT, 1889, Annuaire géologique universel for 1888, tome 5, 1889, p. 1139. (Described in French.)

Orthis salemensis WALCOTT, 1891, Tenth Ann. Rept. U. S. Geol. Survey, pp. 612–613, Pl. LXXXII, figs. 6 and 6a. (The text and figures are copied from Walcott, 1887, pp. 190–191, Pl. I, figs. 17 and 17a, respectively.)

Billingsella salemensis WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 245. (Text copied from Walcott, 1887, pp. 190–191.)

Shell about the average size of the Cambrian species of the genus. Transversely subquadri-lateral; front broadly rounded and slightly sinuate midway; hinge line as long as the greatest width of the shell.

Ventral valve convex, most elevated about one-fourth the distance from the beak to the anterior margin; beak small and incurved to the margin of the medium-sized area; the surface of the area and the foramen have not been observed; mesial sinus broad and shallow, it is marked by a low median rib and laterally by two costæ on each side, a third appearing just outside the sinus.

The dorsal valve, associated in the same hand specimen of limestone, is slightly more convex; frontal margin with a rather deep sinuosity to receive the projection of the ventral valve; median fold broad and but slightly elevated, marked by two or three low costæ; the beak appears in the broken specimen in the collection to be scarcely elevated above the surface of the shell, and to terminate at the cardinal margin; area unknown.

The surface of both valves is marked by fine concentric lines of growth, and low, rounded costæ, varying in number from six or seven, as in the specimens figured, to twelve to fourteen in other specimens.

In the broad costæ and the general aspect of the shell this species is unlike any known to me from the Cambrian, with the exception of *Billingsella whitfieldi* (Walcott), from which, however, it differs in strength and character of costæ and outline of valves.

The specific name is derived from Salem, New York.

FORMATION AND LOCALITY.—**Lower Cambrian:** (319b) Conglomeratic limestones at St. Simon; and (319h) limestone boulders in conglomerate at Metis on the St. Lawrence below Quebec; both in the Province of Quebec, Canada.

^a These localities are represented in the collections of the United States National Museum.

(2b) Limestone just north of Beman Park, in the northeastern part of the city of Troy, Troy quadrangle (U. S. Geol. Survey), Rensselaer County; (22a) limestone in Penrhyn quarries, Middle Granville, Mettawee quadrangle (U. S. Geol. Survey), Washington County; and (367a) limestone about 0.33 mile (0.5 km.) south of John Hulett's farmhouse, 3 miles (4.8 km.) west of South Granville and 4.5 miles (7.2 km.) southwest of Granville, Fort Ann quadrangle (U. S. Geol. Survey); all in New York.

(338d) Limestone 1 mile (1.6 km.) south of Shushan; (21 and 37) shales and limestone 1.5 miles (2.4 km.) south of Salem; (36) limestone 1 mile (1.6 km.) south of Shushan and 3.5 miles (5.6 km.) north-northeast of Cambridge; and (33) limestone on the roadside near Rock Hill schoolhouse, near North Greenwich, about 5 miles (8 km.) northwest of Greenwich; all in the Cambridge quadrangle (U. S. Geol. Survey), Washington County, New York.

Specimens that are doubtfully referred to this species occur at the following locality, the stratigraphic horizon of which is doubtful:

Lower Cambrian: (367b) Sandstone at Lansingburg, north of Troy, Cohoes quadrangle (U. S. Geol. Survey), Rensselaer County, New York.

BILLINGSSELLA STRIATA Walcott.

Plate LXXXVI, figures 4, 4a-c.

Billingsella striata WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 245. (Characterized as below as a new species.)

The form of the ventral valve of this species is much like that of *Billingsella plicatella*. It differs in having a finely striated outer surface, and in the strong development of the main vascular sinuses, and the broader deltidial cavity. The only two specimens of the dorsal valve are nearly flat.

FORMATION AND LOCALITY.—**Middle Cambrian:** (149a) Limestone at the forks of Pole Creek, above Cherry Creek basin, Threeforks quadrangle (U. S. Geol. Survey), Madison County, Montana.

BILLINGSSELLA WHITFIELDI (Walcott).

Plate LXXXVI, figures 5, 5a.

Kutorgina whitfieldi WALCOTT, 1884, Mon. U. S. Geol. Survey, vol. 8, pp. 18-19, Pl. IX, figs. 4, 4a-b. (Described and discussed essentially as below as a new species. The specimens represented by figs. 4, 4a-b are redrawn in this monograph, Pl. LXXXVI, figs. 5 and 5a, respectively.)

Billingsella whitfieldi (Walcott), SCHUCHERT, 1897, Bull. U. S. Geol. Survey No. 87, p. 159. (Merely changes generic reference.)

Billingsella whitfieldi WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 246. (Described and discussed as below, an almost exact copy of the original description, Walcott 1884b, pp. 18-19.)

Shell convex, hinge line straight and a little less than the greatest width of the shell, sides rounding regularly into the slightly convex frontal margin.

Ventral valve fairly convex, elevated along the center to form a flat depressed fold, and sloping somewhat rapidly from this to the lateral and cardinal margins; median elevation with about five rather faintly defined, simple plications, that reach up to the higher portion of the valve; beak small, a little depressed, and rising above the area; cardinal margins straight and diverging from the beak at an obtuse angle; character of area unknown.

Dorsal valve depressed convex, with a rather wide, shallow median depression, and two short plications on each side of it toward the front, which are obsolete in some of the specimens; the area between the cardinal edges and the elevation of the sides of the mesial depression is depressed and corresponds to the flattened lateral slope of the ventral valve.

Surface marked by fine, very clearly defined concentric striae that are crowded together into narrow ridges, and are subparallel to the front and lateral margins of the shell.

Billingsella whitfieldi belongs with the group of species including *B. salemensis*, or shells with coarse plications and very fine concentric striae. The latter species occurs with the *Olenellus* fauna in eastern New York, and *B. whitfieldi* in the Middle Cambrian of central Nevada.

The specific name was given in honor of R. P. Whitfield.

FORMATION AND LOCALITY.—**Middle Cambrian:** (55b) Top of the Eldorado limestone [see Walcott, 1908f, p. 184], west side of Secret Canyon; and (55) shaly limestone at the top of the Eldorado limestone [Walcott, 1908f, p. 184], east slope of Prospect Mountain, in New York Canyon; both in the Eureka district [Hague, 1892, Atlas], Eureka County, Nevada.

Genus *ORUSIA* Walcott.^a

Orthis (*Orusia*) WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 273. (Characterized and discussed essentially as below as a new subgenus.)

Orusia WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 4, Pl. XI, and pp. 142 and 148. (Classification of genus.)

Orthis lenticularis of authors is not an *Orthis* as restricted by Hall and Clarke [1892c, pp. 192–194]. It appears to belong more nearly to the group of species assembled under *Eoorthis*. It departs from *Eoorthis* in its very thin shell, subequally convex valves, small umbonal cavity, and wide variation in form and surface characters.

Type.—*Anomites lenticularis* Wahlenberg [1821, p. 66].

ORUSIA? EUREKENSIS (Walcott).

Plate CI, figures 7, 7a.

Orthis eurekaensis WALCOTT, 1884, Mon. U. S. Geol. Survey, vol. 8, pp. 22–23, Pl. IX, figs. 8 and 8a. (Described as a new species. The specimens represented by figs. 8 and 8a are redrawn in this monograph, Pl. CI, figs. 7a and 7, respectively.)

Protorthis? eurekaensis (Walcott), HALL and CLARKE, 1892, Nat. Hist. New York, Paleontology, vol. 8, pt. 1, p. 232. (Merely changes generic reference.)

Orthis? eurekaensis Walcott, SCHUCHERT, 1897, Bull. U. S. Geol. Survey No. 87, p. 286. (Merely accepts the original generic reference.)

Orthis (*Orusia?*) *eurekaensis* WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 277. (Described and discussed as below.)

General form rounded subquadrate; strongly convex. Surface marked by fine, rounded, radiating ribs, five in the distance of 1 mm. Length of ventral valve, 4 mm.; width, 4.5 mm.; dorsal valve a trifle shorter.

Ventral valve with a high median fold over the umbo, that widens and flattens toward the front margin, which is arched to receive the projecting median depression of the dorsal valve. The umbo curves over to the apex, which overhangs the hinge line. Area low and strongly inclined backward. The interior cast shows that there was a thick pseudospondylium, but no details of it are preserved.

Dorsal valve with a deep, gently curved median sinus or depression that extends from the umbo to the front margin. In the cast strong anterior adductor muscle scars are shown on the sides of the median depression, and just back of them, in the sinus, what may be the smaller posterior adductor scars.

Observations.—This strongly marked shell suggests some of the more convex shells of *Orusia lenticularis* (Wahlenberg); it differs in its fine ribs, deep median sinus in the dorsal valve, and the sharp fold of the ventral valve; also in the presence of a thickened shelf beneath the umbo of the ventral valve that suggests a spondylium; this character, however, is sometimes indicated in *O. lenticularis* (Pl. XCVIII, figs. 1c and 1e).

The specific name is derived from Eureka district, Nevada.

FORMATION AND LOCALITY.—Middle Cambrian: (55b) Top of the Eldorado limestone [Walcott, 1908f, p. 184] west side of Secret Canyon, Eureka district [Hague, 1892, Atlas], Eureka County, Nevada.

ORUSIA LENTICULARIS (Wahlenberg).

Plate XCVIII, figures 1, 1a–p, 2, 2a–k, 3, 3a–b, 6, 6a–c.

Anomites lenticularis WAHLENBERG, 1821, Nova Acta Regiæ Soc. Sci. Upsaliensis, vol. 8, Petrificata telluris Svecanæ, pp. 66–67. (Described in Latin as a new species; see Matthew, 1892, p. 46, for copy of original, and translation.)

Atrypa? lenticularis (Wahlenberg), DALMAN, 1828, K. Svensk. Vet.-Acad. Handl. for 1827, pp. 132–133. (Described in Latin; see Matthew, 1892, p. 46, for copy of original, and translation.)

^a Prior to the definition of the genus *Orusia* the species now placed under that genus were referred to the following genera:

Anomites Wahlenberg [1821, p. 66].

Atrypa? Dalman [1828, p. 132].

Spirifera? von Buch [1834, p. 48].

Atrypa? Hisinger [1837, p. 76].

Atrypa Kjerulf [1857, p. 92; 1865, p. 3].

Orthis Salter [1866, p. 339].

Orthis Davidson [1868, p. 314; 1869, p. 230].

Orthis Kayser [1876, p. 9].

Orthis Roemer [1876, Pl. II, figs. 4a–c].

Atrypa Kjerulf [1879, Pl. XIII].

Orthis Salter and Etheridge [1881, p. 544].

Orthis Brögger [1882, p. 48].

Orthis Walcott [1884b, p. 22].

Orthis Roemer [1885, p. 33].

Orthis Matthew [1892, pp. 46, 48, and 49].

Protorthis? Hall and Clarke [1892c, p. 232].

Orthis? Schuchert [1897, p. 286].

Orthis Matthew [1903, pp. 213, 216, and 217].

- Spirifera? lenticularis* (Wahlenberg), VON BUCH, 1834, Physikal. Abhandl. K. Akad. Wiss. Berlin, p. 48, Pl. I, figs. 13 and 14. (Described in German; see Matthew, 1892, p. 47, for translation.)
- Atrypa? lenticularis* (Wahlenberg) HISINGER, 1837, Lethæa Svecica, p. 76. (Not seen.)

- Orthis lenticularis* (Wahlenberg), DAVIDSON, 1869, British Fossil Brachiopoda, vol. 3, pt. 7, No. 3, pp. 230-232, Pl. XXXIII, figs. 22-28. (Described and discussed, copying Wahlenberg's original description in Latin, 1821, p. 66. Figs. 22, 23 and 24, and 25 are copied from Salter, 1866, Pl. IV, figs. 9a, 9b, and 9c, respectively; figs. 28 and 28a are copied from Davidson, 1868, Pl. XVI, figs. 22 and 22a; and figs. 26, 26a-b are redrawn from the specimen figured by Davidson, 1868, Pl. XVI, figs. 21 and 21a.)
- Orthis lenticularis* (Wahlenberg)?, KAYSER, 1876, Beiträge zur Geologie und Palæontologie der argentinischen Republik, vol. 2, Paleontologischen Theil, Abth. 1, p. 9, Pl. I, figs. 11 and 12. (Characterized and discussed in German; see pp. 767-768 for translation.)
- Orthis* sp., KAYSER, 1876, idem, p. 9, Pl. I, fig. 13. (Characterized in German; see p. 768 for translation.)
- Orthis lenticularis* (Wahlenberg), ROEMER, 1876, Lethæa geognostica, pt. 1, Lethæa palæozoica, Atlas, Pl. II, figs. 4a-c. (No text reference. Fig. 4a is copied from Salter, 1866, Pl. IV, fig. 9a; figs. 4b and 4c are copied from Davidson, 1869, Pl. XXXIII, figs. 26b and 26a, respectively.)
- Atrypa lenticularis* (Wahlenberg), KJERULF, 1879, Sydlige Norges Geologi, atlas, Pl. XIII. (Gives position in vertical section.)
- Orthis lenticularis* (Wahlenberg), SALTER and ETHERIDGE, 1881, Mem. Geol. Survey Great Britain, vol. 3, 2d ed., pp. 544-545, Pl. IV, figs. 8-10. (Text and figures copied from Salter, 1866, p. 339, Pl. IV, figs. 8-10.)
- Orthis lenticularis* (Wahlenberg), BRÖGGER, 1882, Die silurischen Etagen 2 und 3, p. 48. (Specimens from new localities discussed in German.)
- Orthis lenticularis* (Wahlenberg), ROEMER, 1885, Paleontologische Abhandlungen von Dames und Kayser, Bd. 2, Hft. 5, pp. 33-34 (280-281), Pl. I (XXIV), figs. 9a-c. (Occurrences of the species discussed in German. Fig. 9a is copied from Salter, 1866, Pl. IV, fig. 9a; figs. 9b and 9c are copied from Davidson, 1869, Pl. XXXIII, figs. 26b and 26a, respectively.)
- Orthis lenticularis* (Wahlenberg), MATTHEW, 1892, Trans. Roy. Soc. Canada for 1891, vol. 9, sec. 4, No. 5, pp. 46-48, Pl. XII, figs. 9a-d. (Gives original and translation of Wahlenberg, 1821, p. 66, translations of Dalman, 1828, p. 132, and von Buch, 1834, p. 48, and copy of Salter, 1866, p. 339, and describes and discusses species. Specimens from Matthew's material are figured in this monograph, Pl. XCVIII, figs. 3, 3a-b, but as far as can be determined none of these specimens were figured by Matthew, 1892, Pl. XII, figs. 9a-d.)
- Orthis lenticularis strophomenoides* MATTHEW, 1892, idem, p. 49, Pl. XII, figs. 12a-b. (Characterized and discussed as a new variety. The specimens represented by Pl. XCVIII, figs. 1c and 2b, of this monograph, are typical of this proposed variety, but they are drawn from material in the collections of the United States National Museum, and are not the type specimens.)
- Orthis lenticularis* (Wahlenberg), MATTHEW, 1903, Geol. Survey Canada, Rept. Cambrian Rocks Cape Breton, pp. 213-216, Pl. XVII, figs. 1a-d. (Text and figures copied from Matthew, 1892, pp. 46-48, Pl. XII, figs. 9a-d.)
- Orthis lenticularis strophomenoides* MATTHEW, 1903, idem, p. 217, Pl. XVII, figs. 4a-b. (Characterized. Figs. 4a-b are copied from Matthew, 1892, Pl. XII, figs. 12a-b, respectively.)
- Orthis (Orusia) lenticularis* (Wahlenberg), WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 273-276. (Described and discussed essentially as below, giving translation of Kayser's references, 1876, p. 9.)

Matthew [1892, pp. 46-48], in his excellent review of the descriptions of this species, gives a translation of Wahlenberg's original description, together with the Latin; also the descriptions of Dalman [1828, p. 132], von Buch [1834, p. 48], and Salter [1866, p. 339].

He calls attention [1892, p. 47] to the fact that if the reader will compare the several descriptions of this species by the authorities named he will be surprised at the diversity they exhibit. This diversity, Matthew thinks, is due partly to the imperfect descriptions of the earlier writers, but chiefly to the remarkable variability of the species. Matthew recognizes the species in the Upper Cambrian, near St. John, New Brunswick, and has also distinguished three varieties. Through his kindness I had the opportunity of studying the types of the varieties.

Through M. Schmalensee, a collector in the Geological Survey of Sweden, I secured a large and fine series of this species from thin bands of limestone in the *Olenus* and alum shales on Oeland Island and at Hunneberg. I also collected a quantity of the shells in the Upper Cambrian of Manuels Brook, Newfoundland. From this material an attempt has been made to

select a series illustrating the great range of variation in form and surface markings, first, from Sweden; second, from Newfoundland; and third, from New Brunswick. I was not able to obtain satisfactory material from Wales, but Davidson's figures [1869, Pl. XXXIII, figs. 22-28] illustrate fully the peculiarities of the species as it occurs there.

The general form of the shell is fairly well shown by the series of figures on Plate XCVIII; also the great variation in surface characters. Only one specimen was found in which the two valves were united (Pl. XCVIII, figs. 6, 6a-c). The convexity of the two valves is subequal, the ventral being a trifle greater. The cardinal view (Pl. XCVIII, fig. 6c) shows how short the hinge line of both valves is in a specimen where the cardinal extremities are rounded. The side view shows the angle of slope of the areas of the two valves.

A very careful search of the casts of the interior was made for the purpose of illustrating the muscle scars and vascular markings, and in a few instances traces of these have been found. In one illustration (Pl. XCVIII, fig. 1e) the area (pseudospondylium) beneath the umbo of the ventral valve is outlined, also the main vascular sinuses; in another (Pl. XCVIII, fig. 1p), drawn from the cast of a small ventral valve, the area, main vascular sinuses, and the details of the umbonal cavity are clearly shown. The backward extension of the cast of the grooves occupied by the sinuses to the apex of the cavity is very distinct; also the area between them occupied by the path of advance of the scars of the adductor muscles. Matthew [1892, Pl. XII] illustrates some traces of the vascular markings and muscle scars, but they are almost too indefinite to be of value.

In a single specimen of the ventral valve from Oeland Island (Pl. XCVIII, fig. 1p) the cast of the umbonal cavity is nearly as sharp as in some specimens of *Eoorthis remnicha*. The cavity is tripartite (Pl. XCVIII, fig. 1e), the central division being occupied by the diductor muscle scars, and the two lateral divisions are continuous with the ridges representing the casts of the main vascular sinuses. I have been unable to secure any illustrations to show clearly whether there is a deltidium present or not. The delthyrium is clearly shown in several specimens. Casts of the interior of the dorsal valve from Newfoundland (Pl. XCVIII, figs. 2f and 2h) show the presence of crural plates that extend to the bottom of the valve; also short but very definite crura and small depressions beside the latter for the reception of the teeth of the ventral valve. A cast of the ventral valve (Pl. XCVIII, fig. 2d) shows that the dental plates extend to the bottom of the valve; and specimens from Sweden (Pl. XCVIII, figs. 1c and 1e) show that in certain individual ventral valves the dental plates and a transverse arching ridge sharply define the umbonal cavity.

The average size of the specimens from Oeland Island is about 5 by 6 mm. One dorsal valve is 7 by 9 mm. Those from Hunneberg average from 5 to 6 mm., with occasional shells 7 by 8 mm. In Newfoundland great numbers measure 4 by 5 mm., and some have a length of 10 mm. and a width of 12 mm. Matthew [1892, p. 48] states that the average size of the shells in the Acadian rocks is about 5 by 6 mm. Brögger [1882, p. 48] mentions an example from Töien, Christiania, Norway, measuring 10.5 mm. by 12.5 mm.

I have not attempted any detailed description of the species, as it is so variable in form and surface markings. An attempt was made to determine varieties in the material from Sweden and Newfoundland, but there was such a gradation in all of the characters upon which such differentiation might rest that it was finally abandoned. Matthew [1892, p. 48] considers that he has reason for establishing varieties among the New Brunswick forms. Whether these would be of value if a large amount of material were available for comparison is doubtful.

Kayser [1876, Pl. I, figs. 11 and 12] illustrates a shell that is apparently identical with *Orusia lenticularis*, which occurs in the sandstone at Tilcuya, Province of Jujuy, Argentina, in association with *Olenus*, *Agnostus*, etc. He also illustrates [1876, Pl. I, fig. 13] a dorsal valve of a small *Orthis* that in many respects looks more like *O. lenticularis* than figures 11 and 12 of the same work. I very much doubt if they represent this species; in fact, Kayser questions his identification by an interrogation mark. He says of the shell [1876, p. 9]:

Another, much smaller, *Orthis* species occurs in the fine-grained sandstones of Tilcuya, associated with *Olenus*, *Agnostus*, *Arionellus*, *Theca*, and *Orthis saltensis*, which has just been described. The smaller *Orthis* species is

transversely oval in outline, with straight hinge edge, corresponding to the greatest breadth of the shell. The ventral valve is moderately arched, the dorsal somewhat less. The surface of both valves is covered with comparatively strong ribs, arranged in bundles. On the middle of the ventral valve there is an especially well-marked rib or bundle of ribs. Corresponding to this on the dorsal valve there is a well-marked sinus, limited on each side by a strong bundle of ribs.

The form just described agrees in the main so well with the figures given by Salter and Davidson of the small English form identified with Wahlenberg's *lenticularis* that I can hardly doubt its specific identity with the latter.

Of *Orthis* sp. Kayser remarks [1876, p. 9]:

Before me lies a cast from Tilcuya, representing a third *Orthis* species. It is almost equal in size to *O. saltensis*, but differs from it in outline, which is greatly prolonged transversely, the greatest breadth at the hinge edge, and the feeble winglike projection of the hinge corners. This last-named characteristic and the much larger dimensions also distinguish this fossil from *O. lenticularis*. The surface of the shell has been covered with very strong bundles of ribs.

Matthew [1892, pp. 48-49] has named three varieties of *Orusia lenticularis*. I find essentially the same forms in the collections from Sweden and Newfoundland. Two of the varieties, *Orusia lenticularis atrypoides* and *O. lenticularis lyncioides*, have been illustrated in this monograph from Matthew's type specimens. The third variety, *Orusia lenticularis strophomenoides*, occurs associated with specimens of *Orusia lenticularis* in the Swedish material, and does not appear to be of varietal value. It is illustrated in this monograph by Plate XCVIII, figures 1c and 2b.

FORMATION AND LOCALITY.—Upper Cambrian: (9f) Limestones of the *Olenus* zone at Nørnsnæs, west of Christiania; (3231) with *Parabolina spinulosa* at Töien, about 1 mile (1.6 km.) northeast of Christiania; (323m) Étage 2b at Oslo, about 1 mile (1.6 km.) southeast of Christiania; (323n [Brøgger, 1882, p. 48]) Étage 2b at Vestfossen, 10 miles (16.1 km.) west-southwest of Christiania; (323o)^a Étage 2b, in the city of Christiania; (323p) Étage 2b at Slemmestad, about 3 miles (4.8 km.) southwest of Christiania; (323q [Brøgger, 1882, p. 101]) Étage 2b at Kårtveit, in the Christiania region; (323r)^a Étage 2b at Krekling, in Sandsvär; (323s)^a Étage 2b at Gjögrefos, in Sandsvär; (323t) Étage 2b in Hedemarken, east of Lake Mjösen (Miösen), about 40 miles (64 km.) north-northeast of Christiania; (323u)^a Étage 2b at Öxna (Öksna), valley of Glommen River; and (323v [Davidson, 1869, p. 231]) at Egeberg (about 1.5 miles (2.4 km.) southeast of Christiania?); all in Norway.

(310a) Shales of *Olenus truncatus* zone, Oeland Island; (390n) limestones of *Olenus* zone at Hunneberg, western boundary of the Province of Skaraborg; (309m) limestones forming 3c of the *Olenus* series at Alunbruk (alum works), southern part of Oeland Island; (390o) arenaceous shales at Andrarum, 20 miles (32 km.) northwest of Simrishamn, Province of Christianstad; and (390p [Davidson, 1869, p. 231]) at Kinnekulle, northeast of Lidköping, Province of Skaraborg; all in Sweden.

Drift bowlders of gray bituminous limestone at the following localities [Roemer, 1885, pp. 33 and 34]: (386e) Between Vistula and Elbe rivers, in Schleswig-Holstein and Mecklenburg-Schwerin; (386f) near Wismar, Mecklenburg-Schwerin; (386g) near Rostock, Mecklenburg-Schwerin; and (386h) near Meseritz, Province of Posen; all in Germany.

Upper *Lingula* flags at the following localities: (318s)^b Ogof-ddu Cliff, Carnarvonshire; (366s) 5 miles (8 km.) east of Ffestiniog, Merionethshire; (318t)^b Penmorfa Church, Tremadoc, Carnarvonshire; (318u)^b Gwern-y-Barcud; (318v)^b Rhiwfelyn; (318)^b Penmain Pool, west of Dolgelly, Merionethshire; (318a)^b Criccieth, Carnarvonshire; and (318b [Davidson, 1869, p. 232]), near Portmadoc, Carnarvonshire; all in North Wales.

(3) Shaly limestone 300 feet (91.4 m.) above the *Paradoxides* zone; and (6v) shaly limestones 325 feet (99.1 m.) above the Middle Cambrian; both on Manuels Brook, Conception Bay, Newfoundland.

(314i) Shale picked up on beach in Smith Sound, Trinity Bay, Newfoundland.

(10h) Shale on small east branch of Barachois River, 0.75 mile (1.2 km.) north of the crossroad from Boisdale to Upper Leitches Creek; (13q) shales of the Bretonian division of Matthew's [1903, p. 45] section on Gillis Brook, East Bay; (307h)^c in Division C3b? (possibly C3c) of Matthew's section, on McLeod Brook=Barachois River; (307i)^c in Division C3b of Matthew's section on McNeil Brook, east of Mira River; (307j)^c limestone in Division C3b? (possibly C3c) on East Bay, east of Bras d'Or Lake; and (307l)^c limestone in Division C3b? (possibly C3c) on Gillis Brook; all in eastern Cape Breton, Nova Scotia.

Limestone lentils in black shales of Division C3a of Matthew's section at the following localities: (308b [Matthew, 1892, p. 48]) on Germaine Street, St. John; and (308f)^c on King Street, St. John; both in St. John County, New Brunswick.

(389b [Kayser, 1876, p. 9]) Sandstone at Tilcuya, Province of Jujuy, Argentina, South America.

Middle Cambrian: (55b) Top of the Eldorado limestone [Walcott, 1908f, p. 184], west side of Secret Canyon, Eureka district [Hague, 1892, Atlas], Eureka County, Nevada.

(320f) Limestone at Andrarum, 20 miles (32 km.) northwest of Simrishamn, Province of Christianstad, Sweden.

ORUSIA LENTICULARIS ATRYPOIDES (Matthew).

Plate XCVIII, figure 5.

- Orthis lenticularis atrypoides* MATTHEW, 1892, Trans. Roy. Soc. Canada for 1891, vol. 9, sec. 4, No. 5, p. 48, Pl. XII, figs. 11a-b. (Characterized as a new variety; see below for copy. The specimen represented by fig. 11a is redrawn in this monograph, Pl. XCVIII, fig. 5.)
- Orthis lenticularis atrypoides* MATTHEW, 1903, Geol. Survey Canada, Rept. Cambrian Rocks Cape Breton, p. 217, Pl. XVII, figs. 3a-b. (Characterized. Figs. 3a-b are copied from Matthew, 1892, Pl. XII, figs. 11a-b, respectively.)
- Orthis (Orusia) lenticularis atrypoides* (Matthew), WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 276. (Original characterization copied as below.)

The original description by Matthew follows:

This form is comparatively smooth, though the ventral valve is sometimes concentrically wrinkled. This valve is distinguished by a median ridge and somewhat flattened sides, and the dorsal valve has an unusually deep sinus. Size of the known examples, 6 by 6 mm., and 5 by 6 mm. for the two valves.

FORMATION AND LOCALITY.—Upper Cambrian: (308b [Matthew, 1892, p. 48]) Limestone lentils in black shales of Division C3a of Matthew's section, Germaine Street, St. John, St. John County, New Brunswick, Canada.

ORUSIA LENTICULARIS LYNCIOIDES (Matthew).

Plate XCVIII, figure 4.

- Orthis lenticularis lyncoioides* MATTHEW, 1892, Trans. Roy. Soc. Canada for 1891, vol. 9, sec. 4, No. 5, p. 49, Pl. XII, figs. 10a-c. (Characterized as a new variety; see below for copy. The specimen represented by fig. 10a is redrawn in this monograph, Pl. XCVIII, fig. 4.)
- Orthis lenticularis lyncoioides* MATTHEW, 1903, Geol. Survey Canada, Rept. Cambrian Rocks Cape Breton, p. 216, Pl. XVII, figs. 2a-c. (Characterized. Figs. 2a-c are copied from Matthew, 1892, Pl. XII, figs. 10a-c, respectively.)
- Orthis (Orusia) lenticularis lyncoioides* (Matthew), WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 277. (Original characterization copied as below.)

The original description by Matthew follows:

Distinguished by its sharp, strong, radiating ribs, large umbo, and high cardinal area. In some of the larger examples the radiating ribs become subordinate to and are replaced on the newer part of the shell by concentric striæ, reversing the usual position of the ribbed and the smooth parts of the shells of this species. Size of the valves about 6 by 8 mm.

I have illustrated a ventral valve from Matthew's material that is the most strongly marked. The ventral valves are similar to those from Newfoundland represented by Plate XCVIII, figures 2h and 2i.

FORMATION AND LOCALITY.—Upper Cambrian: (308b [Matthew, 1892, p. 49]) Limestone lentils in black shales of Division C3a of Matthew's section, Germaine Street, St. John, St. John County, New Brunswick, Canada.

Genus OTUSIA Walcott.^a

- Billingsella (Otusia)* WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 246. (Mentioned as a new subgenus.)
- Otusia* WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 4, Pl. XI, and pp. 142 and 148. (Classification of genus.)

This name was proposed [1905a, p. 246] to include "*Orthis sandbergi*" of N. H. Winchell, which was the only species known at the time the genus was named. One new species, *Otusia utahensis*, has been added since. The generic and specific characters are included in the description of the species.

OTUSIA SANDBERGI (N. H. Winchell).

Plate XCIII, figures 4, 4a-d.

- Orthis sandbergi* N. H. WINCHELL, 1886, Fourteenth Ann. Rept. Geol. and Nat. Hist. Survey Minnesota, p. 318, Pl. II, figs. 8 and 9. (Described as a new species.)
- Orthis (?) sandbergi* Winchell, WALCOTT, 1899, Mon. U. S. Geol. Survey, vol. 32, pt. 2, pp. 452-453, Pl. LXI, figs. 2, 2a-d. (Described and discussed as on p. 770. Figs. 2, 2a-d are copied in this monograph, Pl. XCIII, figs. 4, 4a-d, respectively.)

^a Prior to the definition of the genus *Otusia* the type species was described under the genera *Orthis* N. H. Winchell [1886, p. 318] and *Orthis* ? Walcott [1899, p. 452].

Billingsella (Otusia) sandbergi (Winchell), WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 246-247. (Described and discussed essentially as in preceding reference, p. 769, and as below.)

Shell small, transverse, subquadrate in outline, exclusive of the acute cardinal extremities. Valves slightly convex, with a straight hinge line longer than the greatest width of the shell; cardinal area narrow, but well developed on each valve and divided by a rather large open delthyrium.

The ventral valve slightly flattened at the cardinal extremities, rising toward the center with a convex triangular swelling, broadening from the narrow beak to the front; beak small, rounded, and extending slightly beyond the hinge line. Dorsal valve flattened at the cardinal extremities, with well-marked rounded ridges rising between them, and a rather broad, well-defined median sinus; beak very small, slightly encroaching upon the hinge line.

Surface marked by fine, regular, radiating striae, between which one or more faint intermediate striae are sometimes visible; under favorable conditions very fine concentric striae can be seen, and there are also usually present more or less distinctly marked lines of growth.

Very little is known of the interior of the ventral valve. Two fragments of the posterior portion show a broad delthyrium, strong teeth, and a broad umbonal cavity opposite the delthyrium. In the ventral valve the area is narrow and divided by a broad delthyrium, which has a strong cardinal process that extends forward nearly three times the length of the area. Anteriorly, it rests on a broad ridge that extends forward, gradually broadening out and disappearing at the anterior margin of the shell.

In my former description [1899, p. 453] I stated that "the generic character of this species has not been fully ascertained, but the material from the Yellowstone National Park and specimens from the typical locality at Red Wing, Minnesota, lead me to think that this can not be referred to the genus *Billingsella*. It appears to be an *Orthis* of the *Plectorthis* group of Hall and Clarke." A closer study of this species and the forms referred to *Billingsella* led me [1905a, p. 246] to refer it to *Otusia* on account of its surface characters, the character of the delthyrium in the two valves, and the strong cardinal process and median ridge in the dorsal valve.

A comparison of the specimens of this species from the type locality at Red Wing, Minnesota, with those from the Yellowstone National Park shows the two shells to be specifically identical as far as the comparison of casts in sandstone can be made with well-preserved shells on the surface of limestone.

The specific name was given in honor of Dr. J. H. Sandberg, of Red Wing, Minnesota, who first called attention to the type locality of this species.

FORMATION AND LOCALITY.—Upper Cambrian: (86a) "St. Croix sandstone" near Red Wing, Goodhue County, Minnesota.

(302f) Upper part of the Gallatin formation, north side of Elk Pass, between Buffalo and Slough creeks, Yellowstone National Park, Livingston quadrangle (U. S. Geol. Survey), Montana.

OTUSIA UTAHENSIS n. sp.

Plate LXXXIX, figures 3, 3a-c.

This species is represented by several fragments of the two valves. One of the specimens, represented by figure 3, indicates the general outline of the ventral valve, and figure 3b that of the dorsal valve. The surface is marked by concentric lines and small ridges of growth and numerous fine, rounded, radiating ribs that increase by the division of the ribs as they are lengthened by the growth of the shell. A shallow median sinus occurs on the dorsal valve, and a rounded median ridge on the ventral valve.

The largest dorsal valve has a width of 9 mm. at the hinge line, with a length of about 6 mm.

The generic reference is made on account of the general resemblance of this form to *Otusia sandbergi* (N. H. Winchell). It differs from the latter in outline and in the rounded character of the ribs.

FORMATION AND LOCALITY.—Middle Cambrian: (31c) About 900 feet (274.3 m.) above the Brigham quartzite and 3,300 feet (1,005.8 m.) below the Upper Cambrian in the limestone forming 1b of the Ute limestone [Walcott, 1908f, p. 196], in Blacksmith Fork Canyon, about 10 miles (16.1 km.) east of Hyrum, Cache County; (32e) limestone at the

same horizon as that of No. 31c, just south of the south fork of Paradise Dry Canyon (locally known as East Fork), east of Paradise, Cache County; and (33r) *limestones faulted against the Cambrian quartzites in a canyon about 1 mile (1.6 km.) east of Cricket Spring, Cricket Range (locally known as the Beaver River Range or the Beaver Mountains), northwest of Blackrock, Millard County; all in Utah.*

Genus WYNNIA Walcott.^a

Wynnica WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 4, Pl. XI, and pp. 142 and 148. (Classification of genus.)

The description of the type species includes all that is known of this genus. The material is poor, but sufficient to indicate that the species belongs to an undefined genus. It differs from *Orthis* (restricted) in the presence of the large vascular sinuses of the ventral valve and pointed apex of the dorsal valve. The latter is of the type of the apex of the valves of *Nisusia festinata* (Billings). From *Billingsella* it differs in the absence of dental plates and deltidium in the ventral valve.

Type.—*Orthis warthi* Waagen.

The generic name is given in honor of Mr. Arthur B. Wynne, of the Geological Survey of India.

WYNNIA WARTHI (Waagen).

Text figures 68A-A'; Plate LXXXIX, figures 4, 4a-f.

Orthis warthi WAAGEN, 1891, Mem. Geol. Survey India, Paleontologia Indica, 13th ser., Salt Range Fossils, vol. 4, pt. 2, pp. 102-104, Pl. I, figs. 12-15, Pl. II, figs. 1 and 2. (Described and discussed as a new species. The specimen represented by fig. 12b is redrawn in this monograph, Pl. LXXXIX, fig. 4a. The specimen represented by fig. 14 is redrawn in the same position on Pl. LXXXIX (fig. 4b) of this monograph and in text fig. 68A'. Different views of the same specimen are shown in this monograph, Pl. LXXXIX, fig. 4, and text fig. 68A, both of which drawings are of the same shell in the same position. The text figures are the correct representations in each case. Pl. II, figs. 2a, 2b, and 2c, are copied in this monograph, Pl. LXXXIX, figs. 4e, 4d, and 4f, respectively.)

Shell small, biconvex, subcircular to broad oval in outline. Exterior surface unknown. Cast of interior of ventral valve strongly convex. Apex slightly incurved over a rather high area that slopes forward at an angle of about 45° to the hinge line. The area is formed of two narrow sides separated by a large triangular delthyrium without traces of a deltidium; the narrow, elongate sides are slightly concave and have in the cast a narrow raised margin next to the delthyrium. The dorsal valve is less convex than the ventral, its area slopes forward from the hinge and at the apex of the valve bends slightly forward, giving an effect somewhat like that of the ventral valve of *Nisusia festinata* (Billings), only very much reduced. The casts of the interior of the ventral valve show two strong vascular sinuses and a faintly defined muscle area. This has an outline not unlike that of the diductor scars in the ventral valve of *Billingsella romingeri* (Barrande) (Pl. XC, fig. 2g). The large main vascular sinuses also extend forward in the same manner in the two species. The illustrations of the interior of the ventral valve of *Wynnica warthi* (Pl. LXXXIX, figs. 4 and 4a) fail to show the outline of the muscle area as well as it is shown in the specimen represented by figure 4, so I have inserted text figures 68A and 68A', which are drawn from the same specimen.

The casts of the interior of the dorsal valve show a median depression with a few radiating lines, and a few very fine radiating lines extending from the apex a short distance forward. In addition, by reflected light, the outlines of the anterior and posterior adductor scars can be seen on the posterior half of the valve (Pl. LXXXIX, fig. 4c).

The longest ventral valve in the collection has a length and width of 9 mm. The dorsal valve is a little shorter.

FIGURE 68.—*Wynnica warthi* (Waagen). A, Cast of interior of a ventral valve (X 4). The shell was compressed laterally and hence the muscle scars and sinuses are crowded toward the center. A', Posterior view of same specimen, showing broken-off beak.

The specimen from which figures 68A and 68A' are drawn is incorrectly figured on Plate LXXXIX, figures 4 and 4b, of this monograph, and is the specimen figured by Waagen [1891, Pl. II, fig. 14]. It is from the upper portion of the "*Necobolus* beds" at Chél Hill, Salt Range, India (Geol. Survey India, Cat. No. 4/124).

^a Prior to the definition of the genus *Wynnica* the type species was placed under *Orthis* [Waagen, 1891, p. 102].

Observations.—Waagen [1891, p. 102] describes this shell at length and also gives a number of illustrations that are more or less diagrammatic. Through the courtesy of Doctor Holland, the director of the Geological Survey of India, I have been able to study the type specimens. I can not see as much in them as Waagen did, but as far as my observations go they agree with his, except that the characters shown on the specimen represented by his figure 15 [1891, Pl. I] and figure 1 [1891, Pl. II] appear to me to be the result of fracture caused by compression of the original shell and not to be muscle scars, etc., as interpreted by Waagen [1891, Pls. I and II].

The differences between this shell and the nearest known forms are mentioned under the description of the genus (see p. 771).

The specific name is given in honor of Dr. H. Warth, of the Geological Survey of India.

FORMATION AND LOCALITY.—Middle Cambrian: (357d [Waagen, 1891, p. 104]) "Concretionary shales of the Khussak group" at several localities between Chél Hill and Kiura (Khewra), eastern part of Salt Range, India.

Subfamily EOORTHINÆ Walcott.

Genus EOORTHIS Walcott.^a

[*εως*, dawn; and *ὀρθος*, straight.]

Not *Plectorthis* HALL and CLARKE, 1892, Nat. Hist. New York, Paleontology, vol. 8, pt. 1, pp. 194-195. (Characterized as a new genus; see below for copy. This genus, as now restricted, is not known to occur in the Cambrian.)

Orthis (*Plectorthis*) WALCOTT [not (HALL and CLARKE)], 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 257-259. (Original characterization copied and genus discussed somewhat as below.)

Plectorthis GRABAU and SHIMER (in part) [not HALL and CLARKE], 1907, North American Index Fossils, vol. 1, pp. 250 and 251. (Characterized. Includes both true *Plectorthis* and *Eoorthis*.)

Eoorthis WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 3, pp. 102-104. (Described and discussed as below as a new genus.)

Eoorthis WALCOTT, 1908, idem, vol. 53, No. 4, Pl. XI, and pp. 142 and 148. (Classification of genus.)

In their subdivision of the genus *Orthis* Dalman, Hall and Clarke [1892c, p. 192] restricted the genus *Orthis* to the group of which *Orthis callactis* Dalman is the type, and, among American forms, *Orthis tricenaria* of the Trenton and Hudson faunas. These forms show the existence of a transverse apical plate in the delthyrium of the ventral valve. The name *Plectorthis* was proposed for a second group, of which *Orthis plicatella* was made the type (Pl. XCVI, figs. 4, 4a), and of this the authors [1892c, p. 194] say:

This is a persistent form, which in American faunas, so far as known, is limited to the Trenton and Hudson River formations. While it retains the strong external ribs of the typical *Orthis*, these are not invariably simple (*O. fissicosta* Hall; *O. triplicatella* Meek; *O. aequalis* Hall [not Davidson]; *O. jamesi*, Hall) (Pl. XCVI, figs. 5, 5a-c). The cardinal area of the pedicle valve is comparatively low and the valves are subequally convex. In the interior, the character of the muscle scars, dental lamellæ and cardinal process is essentially the same as in group I (*Orthis*), and the minute structure of the shell appears to be in precise agreement with that of *O. calligramma* though no evidence of tubulose costæ has been observed. In *Orthis jamesi*, which is placed in this association, there is occasionally a deviation toward the resupinate contour exemplified in group IV (*Orthis subquadrata*) and group V (*Orthis sinuata*).

In the Cambrian faunas I find a group of species intermediate between the typical forms of *Billingsella* and of *Orthis*, as limited by Hall and Clarke [1892c, p. 193], which I have referred for a long time to Hall and Clarke's *Plectorthis*, placing that genus as a subgenus of *Orthis*.

^a The synonymy for this genus does not give a complete record of the various genera under which the species now included in *Eoorthis* were formerly placed; it gives only those references in which the genus is discussed or described. To complete the record for the species taken up in this monograph the following mere generic references are listed:

Orthis de Verneuil and Barrande [1860, p. 532].
Orthis Kjerulf [1865, p. 1].
Orthis Barrande [1868a, p. 99; 1868b, p. 690].

Orthis (*Plectorthis*) Moberg and Segerberg [1906, p. 69].
Nisusia Walcott [1908d, p. 97] (hy mistake).

This Cambrian group of shells which I now refer to a distinct genus may be defined as follows, the type of the genus being "*Orthis remnicha*" Winchell (Pls. XCI and XCII):

Diagnosis.—Shells subquadrate to transversely elongate; with or without median fold and sinus; valves subequally convex. Hinge line straight, usually forming nearly the greatest diameter of the shell. Cardinal extremities broadly angular, rarely acuminate. Surface with radiating ribs and striæ which may be crossed by concentric growth lines and striæ. The ribs increase by interpolation.

The ventral valve has the umbo more or less elevated over a hinge line, the apex acute and usually incurved. The area is rather broad, flat or incurved, and transversely striated. Teeth short and supported by dental plates that extend to the bottom of the valve, bounding a space (pseudospondylium) including the main vascular sinuses and area of attachment of the adductor muscle scars. Delthyrium open or partly closed by a convex deltidium. The adductor muscle scars are included within a narrow median area beneath the umbo on each side of the median line, and the diductors in a more or less flabelliform area outside of the main vascular sinuses. Pedicle scars unknown.

Dorsal valve with low umbo and slightly incurved apex; area well developed, with a broad delthyrium. Deltidial cavity with a straight, simple, cardinal process. Dental sockets small, with short crura. The adductor muscle scars are small, the anterior being nearer the median ridge, which usually extends forward from the base of the cardinal process.

Shell structure dense, with a minutely granular groundmass. Sections vertical to the outer surface, however, show a few laminations of growth, but no fine fibers; sections on the plane of the surface show a few coarse irregular fibers resembling matted wood pulp; a dense granular groundmass that is penetrated here and there by irregular openings of varying size. The openings or pores appear to be confined to one or more lamellæ of the shell and not to pass through it from inner to outer surface, as in *Orthis (Dalmanella) parva* and allied punctate orthoids. The openings are usually indicated by minute scattered dark spots.

Type.—*Orthis remnicha* Winchell.

Observations.—The Cambrian species referred to *Eoorthis* have relatively thin shells that retain on the interior surfaces but slight traces of the muscle scars and vascular markings, except in the umbonal cavity. *Eoorthis* may be distinguished from *Orthis* (s. s.) by (1) its ribs increasing by interpolation; (2) its strongly defined pseudospondylium; (3) its relatively thin shell; and (4) its dense, nonfibrous shell structure. The last three characters also distinguish it from *Plectorthis* and other subgenera of *Orthis*. *Eoorthis* may be considered as the possible connecting link between *Billingsella* and the orthoids of the Ordovician.

The geological range of *Eoorthis* is from the upper portion of the Middle Cambrian through the Upper Cambrian and into the lower portion of the Ordovician.

Two of the species from strata referred to the Middle Cambrian are represented by material too imperfect for specific description; they occur with *Paradoxides* in Bohemia, and it is not improbable that they will be found to belong to some other genus. The remaining one of the three species referred to the Middle Cambrian is *E. wichitaensis*, which occurs in the upper portion of the Middle Cambrian and base of the Upper Cambrian, and *E. hastingsensis*, which occurs in the Middle Cambrian (*Paradoxides* zone).

EOORTHIS AGRESTE (Walcott).

Plate LXXXIX, figures 6, 6a.

Orthis (Plectorthis) agreste WALCOTT, 1906, Proc. U. S. Nat. Mus., vol. 30, p. 570. (Described as below as a new species.)

Shell transverse, subsemicircular; a ventral valve 9 mm. in length has a width of 12 mm. and a hinge line 10.5 mm. in length; ventral valve moderately and regularly convex, with the apex curved down to an area that is slightly inclined forward from the hinge line. The details of the cardinal area are unknown.

Surface marked by rounded radiating ribs and interspaces, 6 ribs in a space of 3 mm. near the front margin; a few of the ribs bifurcate, but most of them extend from the umbo to the front margin; the ribs are crossed by fine concentric striæ and strong lines of growth.

Observations.—This shell is characterized by its regular convexity and the uniformity of the rounded, radiating ribs.

FORMATION AND LOCALITY.—Middle Cambrian: (C28) Upper part of the thin-bedded gray limestone at the base of the Changhia formation [Blackwelder, 1907a, p. 32 (first list of fossils), and fig. 6 (bed 20), p. 25] 1 mile (1.6 km.) east-southeast of Changhia, Shantung, China.

EOORTHIS ATAVA (Matthew).

Plate XCV, figures 7, 7a-b.

Strophomena atava MATTHEW, 1893, Trans. Roy. Soc. Canada for 1892, 1st ser., vol. 10, sec. 4, No. 7, pp. 102-103, Pl. VII, fig. 8a-f. (Described and discussed as a new species; see below for copy. The specimens represented by figs. 8c, 8a, and 8b are redrawn in this monograph, Pl. XCV, figs. 7, 7a-b, respectively.)

Rafinesquina? atava (Matthew), SCHUCHERT, 1897, Bull. U. S. Geol. Survey No. 87, p. 338. (Merely changes generic reference.)

Orthis (*Plectorthis?*) *atava* (Matthew), WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 259-260. (Original description copied and species discussed as below.)

Strophomena? atava Matthew, MOBERG and SEGERBERG, 1906, Medd. från Lunds Geol. Fältklubb, Ser. B, No. 2 (Atryck ur K. Fysiografiska Sällskapets Handl., N. F., Bd. 17), Pl. II, figs. 7, 7a-b. (No text reference. Figs. 7, 7a-b, in common with the remaining figures on Pl. II of Moberg and Segerberg's paper, were copied from a preliminary photograph of Pl. XCV of this monograph.)

The original description by Matthew follows:

Narrow semicircular. Valves slightly arched, rather wider than the hinge line, compressed at the cardinal angles; sides of the valves nearly straight behind, regularly rounded in front.

Ventral valve moderately convex, highest and somewhat angulated at the middle of its length. Umbo inconspicuous and appressed to the very narrow area.

Dorsal valve somewhat concave, especially toward the umbo, which is depressed to the general level of the valve.

The interior of the ventral valve has characters intermediate between those of *Orthis* and *Strophomena*. The ridges inclosing the cardinal muscles are shorter and closer at their extremities than in *Strophomena*, and the scar of the adductor muscle is broader and shorter, but extends halfway to the front of the valve. There is a low, sharp ridge at the umbo between the branches of the posterior cardinal muscle, and the ventral cavity is faintly outlined in front. Another cast of the ventral valve of a larger individual, perhaps of this species, shows the impressions of the muscles more distinctly; in this the impression of the adductor muscle is much nearer to the hinge, being about two-thirds from the front of the valve. There is a low callus in front of the imprint of the adductor muscle.

A partly decorticated example of the dorsal valve exhibits a small bifid scar at the hinge line, due to the adductor muscle. There is no median ridge, such as is found in *Orthis*, the median sinus being almost obsolete. In front of the impression of the adductor muscle is a small, low callus.

Sculpture: This consists of sharply raised, rounded, radiating ridges, slightly crenulated by obscure, transverse lines. These ribs are of varying size, every third or fifth rib being larger than the others. These large ribs extend outward from the umbo, and the smaller ones are intercalated between them, or spring from them. On the dorsal valve there are two main ribs in the sinus of the valve and three others extending to the lateral margins; smaller ribs are intercalated between these. On each side of the group of ribs on the middle third of the shell are four fainter, but more strongly arched groups of ridges which throw off minor ridges at the back, directed toward the lateral margins. On the ventral valve the small ribs are almost all intercalated and do not spring from the back of the primary ribs, as in those of the dorsal valve.

Size: Length, 12 mm.; width, 14 mm. Height of area of dorsal valve, 0.5 mm.; of ventral valve, 1 mm. A valve supposed to be of this species is 15 mm. long and 19 mm. wide.

Observations.—With the available data this species appears to be quite as near to *Eoorthis* as any described genus. It does not appear to belong with the typical forms of *Strophomena* or *Rafinesquina*. The surface ribs, increasing by interpolation, and possibly bifurcation, and the form of the pseudospondylium in the ventral valve, strongly suggest a relationship with *Eoorthis*. It will probably require better preserved material to determine satisfactorily the correct generic reference for the species.

FORMATION AND LOCALITY.—Upper Cambrian: (308a [Matthew, 1893b, p. 103]) Dark shales of division C3a of Matthew's section of the St. John formation, Navy Island, St. John Harbor, St. John County, New Brunswick, Canada.

EOORTHIS BAVARICA (Barrande).

Plate XCVII, figure 4.

Orthis bavarica BARRANDE, 1868, Faune silurienne des environs de Hof, en Bavière, p. 99, fig. 76. (Described in French as a new species; see below for translation. Fig. 76 is reproduced in this monograph, Pl. XCVII, fig. 4.)

Orthis bavarica BARRANDE, 1868, Neues Jahrb. für Mineralogie für 1868, p. 690, unnumbered plate, fig. 76. (Copy of preceding reference.)

Orthis sp., POMPECKJ, 1896, Tremadoc Fossilien bei Hof, p. 4. (Discussed in German; see below for statement of probable relationships.)

The original description by Barrande follows:

This very rare species is only represented by two specimens, reduced to a single valve, of which the less imperfect of the two is figured. It has been deformed by compression, but we recognize that it represents the ventral valve, the beak of which appears remarkably acute and projecting, doubtless by reason of compression. This valve shows a barely indicated sinus, very shallow, but rather broad on the frontal contour. The surface is ornamented with projecting longitudinal striæ, close together, most of which end at the beak, but some are bifurcated in their extension. A trace of some concentric striæ is seen.

Length, 14 mm.; breadth, somewhat reduced by compression, 9 mm.

Pompeckj [1896a, p. 4] mentions the finding of two impressions of a species of *Orthis* agreeing in form with *E. bavarica* (Barrande) at Neuhof, near Hof. The species differs in having a sharper, higher rib intercalated between every three or four finer ribs, while the ribs of *E. bavarica* are all equally strong. The variation in the strength and number of the ribs in species of *Eoorthis* is often so great that it may be that the form mentioned by Pompeckj [1896a, p. 4] will prove to be only a variation of *Eoorthis bavarica*.

From the description and illustration, I think this species should be referred to *Eoorthis*.

FORMATION AND LOCALITY.—Passage beds between the Upper Cambrian and the Ordovician: (303c [Barrande, 1868a, p. 99] suburbs of Hof; and (303f [Pompeckj, 1896a, pp. 7 and 8] railway cut near Schellenberg, a little distance back of the railway station at Neuhof, near Hof; both in Bavaria, Germany.

EOORTHIS CHRISTIANIÆ (Kjerulf).

Plate XCV, figures 1, 1a-h.

Orthis christianiæ KJERULF, 1865, Veiviser ved Geologiske Excursioner i Christiania Omegn, p. 1 and figs. 8a-c, p. 3. (Locality given in Norwegian.)

Orthis christianiæ Kjerulf, BRÖGGER (in part), 1882, Die silurischen Etagen 2 und 3, p. 48, Pl. X, figs. 14a-c. (Mentions specimens from both the *Ceratopyge* slate and *Ceratopyge* limestone and thus probably includes the two species, *Eoorthis christianiæ* and *E. daunus*. See below.)

Orthis (Plectorthis) christianiæ (Kjerulf), WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 260-261. (Discussed somewhat as below.)

Orthis (Plectorthis) christianiæ (Kjerulf), MOBERG and SEGERBERG (in part), 1906, Medd. från Lunds Geol. Fältklubb, Ser. B, No. 2 (Aftryck ur K. Fysiografiska Sällskapet's Handl., N. F., Bd. 17), p. 69, Pl. II, figs. 1, 1a-h; Pl. III, figs. 12 and 13. (Described and discussed in Swedish. Includes *Eoorthis daunus* and *E. tullbergi*. Figs. 1, 1a-h, in common with the remaining figures on Pl. II of Moberg and Segerberg's paper, were copied from a preliminary photograph of Pl. XCV of this monograph.)

The general form and character of this shell as it occurs in the shales are shown by the figures illustrating it. It appears to differ from any described species in the peculiarity of the bifurcation of the radiating ribs. In all the species I have referred to *Eoorthis* the increase in the number of ribs is by interpolation and not by true bifurcation. In *E. christianiæ* the increase is by both methods, as shown by figures 1a, 1b, and 1g. The reference to *Eoorthis* is somewhat doubtful, as there are not sufficient data to base a reference on the characters of the interior, cardinal areas, or convexity of the valves.

I have received a large number of specimens from Norway and Sweden labeled "*Orthis christianiæ*." After a study of all the available material only the shells from the argillaceous shale of Russelökken and Töien, Norway, and of Oeland Island, Sweden, appear to belong to the species. The shells in the *Ceratopyge* limestone (*Eoorthis daunus*) have ribs that increase in number by interpolation of ribs in the interspaces between the older ribs, and a second species (*E. wimani*), that occurs in both the shale and the limestone, has simple ribs with few

interpolated beyond the umbo. Another transverse form has simple strong ribs that increase in number by the interpolation of a few new ribs.

Brögger's illustrations of this species [1882, Pl. X, figs. 14a-c] suggest *E. daunus* more than the typical form of *E. christianix*, as I understand and interpret it. "*Orthis parva*" Dalman (Pl. XCVI, figs. 6, 6a-g) has sometimes been referred to *E. christianix*.

Gagel [1890, p. 34] described the form usually found in the limestone, stating that the surface is covered with strong, dichotomous ribs. He found it in drift blocks of the *Ceratopyge* limestone near Belschwitz, East Prussia; and of glauconitic limestone near Prussian Holland, and near Wehlau, East Prussia, Germany.

Roemer [1885, p. 36] calls attention in his description of the drift in the North German plain to the fact that Remelé [1885, pp. 695-698] was the first to identify with certainty blocks of the *Ceratopyge* limestone of Sweden in the drift of Germany, the presence of a form like *E. christianix* being part of the evidence. This shell is probably *E. daunus*. Roemer [1885, p. 36] states in description of the *Ceratopyge* limestone that a small "*Orthis* (? *Orthis christianix* Kjerulf)" predominates.

The specific name is derived from Christiania, Norway.

FORMATION AND LOCALITY.—Upper Cambrian: (323x) *Ceratopyge* slate, at Russelökken; and (323y) *Ceratopyge* slate at Töien; both near Christiania, Norway.

(310d) *Ceratopyge* slate, at Borgholm, Oeland Island, Sweden.

(309e) Shales of the *Acerocare* zone at Åkarp smölla, midway between Kågeröd and Röstänga, Province of Malmöhus, Sweden.

EOORTHIS DAUNUS (Walcott).

Plate XCV, figures 2, 2a-c.

Orthis christianix BRÖGGER (in part) [not KJERULF], 1882, Die silurischen Etagen 2 und 3, p. 48, Pl. X, figs. 14a-c.

(Mentions specimens from both the *Ceratopyge* slate and *Ceratopyge* limestone and thus probably includes the two species, *Eoorthis christianix* and *E. daunus*.)

Orthis christianix ROEMER [not KJERULF], 1885, Paleontologische Abhandlungen von Dames und Kayser, Bd. 2, Hft. 5, pp. 36, 37, and 38. (Mentioned in German, in review of literature.)

Orthis christianix REMELÉ [not KJERULF], 1885, Katalog der beim intern. Geologen-Congress zu Berlin ausgestellten Geschiebesammlung, p. 6. (Locality mentioned.)

Orthis christianix GAGEL [not KJERULF], 1890, Beitr. zur Naturkunde Preussens, von Physikal.-oekonom. Gesell. Königsberg, No. 6, pp. 10 and 34, Pl. II, figs. 22a-b. (Described and new localities mentioned in German.)

Orthis christianix POMPECKJ [not KJERULF], 1902, Neues Jahrb. für Mineralogie, Bd. 1, p. 7. (Occurrence mentioned, in German.)

Orthis (*Plectorthis*) *daunus* WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 261. (Characterized as a new species.)

Orthis (*Plectorthis*) *daunus* WALCOTT, MOBERG and SEGERBERG, 1906, Medd. från Lunds Geol. Fältklubb, Ser. B, No. 2 (Aftryck nr K. Fysiografiska Sällskapets Handl., N. F., Bd. 17), p. 69, Pl. II, figs. 2, 2a-c. (Characterized in Swedish. Figs. 2, 2a-c, in common with the remaining figures on Pl. II of Moberg and Segerberg's paper, were copied from a preliminary photograph of Pl. XCV of this monograph.)

The illustrations show the principal characters of this species. It differs from *Eoorthis christianix* in having simple ribs that increase in number toward the front and lateral margins of the shell by interpolation of new ribs; no true bifurcation of the ribs was observed. A strong median sinus occurs on specimens of the dorsal valve in both shale and limestone. The shell is fibrous and impunctate. No traces have been seen of the fine, rounded, radiating striæ that occur on the broader ribs and interspaces of *E. christianix*. This species differs from *E. wimani* in its more transverse form and less simple ribbing of the shell.

Moberg and Segerberg [1906, pp. 69-70] regard this form as one of the variations of *E. christianix*. This may be a correct view, but I am not prepared, after a careful study of the material before me, to accept it. To support such an interpretation we should find, in a very full series of *E. christianix* from the same bed or matrix, the gradations or varieties that I have named *tullbergi* and *daunus*.

FORMATION AND LOCALITY.—Passage beds between the Upper Cambrian and Ordovician: (386) Drift blocks of *Ceratopyge* limestone near Belschwitz; (386a) drift blocks of "Glauconite limestone" near Prussian Holland,

90 miles (145 km.) south-southwest of Königsberg; and (386b) drift blocks of "Glauconite limestone" near Wehlau, 30 miles (48 km.) east of Königsberg; all [Gagel, 1890, p. 34] in East Prussia, Germany.

(323z) *Ceratopyge limestone* at Töien, near Christiania; and (8x) *Ceratopyge limestone* at Slemmestad, about 3 miles (4.83 km.) southwest of Christiania; both in Norway.

(323h) Blue *Ceratopyge limestone* at Vestfossen; and (323f) lower part of the *Ceratopyge limestone* at Vestfossen; both [Brögger, 1882, p. 17] 10 miles (16.1 km.) west-southwest of Christiania, Norway.

(310j) *Ceratopyge limestone* at Borgholm; and (310) [Moberg and Segerberg, 1906, description of Pl. III] *Ceratopyge limestone* (zone 4) at Ottenby; both on Oeland Island, Sweden.

EOORTHIS DESMOPLEURA (Meek).

Plate XCVI, figures 1, 1a-r.

Not *Orthis coloradoensis* SHUMARD, 1860, Trans. Acad. Sci. St. Louis for 1856-1860, vol. 1, p. 627. (Referred in this monograph to *Billingsella*.)

Orthis coloradoensis MEEK [not SHUMARD], 1870, Proc. Am. Philos. Soc., vol. 11, No. 84, p. 425. (Described as a new species.)

Orthis desmopleura MEEK, 1872, U. S. Geol. and Geog. Terr., Geol. Survey Wyoming, Prelim. Rept., p. 295. (Merely proposed as a new specific name, *coloradoensis* being preoccupied.)

Orthis (Plectorthis) desmopleura (Meek). WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 261. (Characterized.)

This shell has the general form and external characters of *E. wichitaensis* (Walcott). It differs in being less convex and in the details of the radiating ribs. The illustrations of the two species will serve as a basis of comparison. *Eoorthis desmopleura* differs from *E. remnicha* (N. H. Winchell) in its uniformly smaller size, less convexity, and in the details of the radiating ribs. The ribs have a wide range of variation, but when from the same character of matrix they are all of the same type and the shells grade from one to the other. The ventral valves of young shells 2 to 3 mm. long are highly convex and usually appear to be a little longer than wide; if in such shells the surface striæ are in sharply elevated fasciculæ, the result is to all appearances a rhynchonelloid shell.

The interior of the ventral valve shows a narrow area, broad delthyrium, spondylium almost free from the bottom of the valve, and a median septum that may have supported the front end of the spondylium. In young and strongly convex shells the spondylium is narrow and very strongly defined. The narrow area of the dorsal valve is divided by a broad delthyrium, in the center of which is a very slightly developed cardinal process.

The Wyoming variety of this species occurs in abundance in the Bighorn Mountains. The specimens illustrated on Plate XCVI show the characteristic features of the species as it occurs in Colorado, and also some phases of it not observed there. The typical form is illustrated by figure 1h. For the variety the name of *E. desmopleura nympha* is used (Pl. XCVI, fig. 2).

Eoorthis hamburgensis (Walcott) [1884b, p. 73] is closely related to *E. desmopleura* and may be identical with it. *Eoorthis melita* (Hall and Whitfield) [see *Leptæna melita* Hall and Whitfield, 1877, p. 208] from the Pogonip Lower Ordovician limestone is near to the less convex, more evenly striated forms of *E. desmopleura*. It is probably not more than a variety of the latter. Schuchert's reference of the species *L. melita* to *Dalmanella* [1897, p. 202] does not appear to be correct, as it has the pseudodeltidium of *Eoorthis*.

FORMATION AND LOCALITY.—Lower Ordovician: (360f) *Siliceous limestone* at Glen Eyre, Queens Canyon, north-east of Manitou; (360a) red siliceous limestone on west side of Trout Creek below Bergen Park, 7 miles (11.2 km.) north-northwest of Manitou; (186 and 186a) near line of contact between red and gray Ordovician limestone, in siliceous red limestone about 30 feet (9.1 m.) above the pre-Cambrian rocks, Williams Canyon, Manitou; (187) red siliceous limestone 105 to 122 feet (32 to 36.7 m.) above the pre-Cambrian rocks, 2 miles (3.2 km.) below Manitou Park Hotel; and (360) red siliceous limestone near Colorado Springs; all in El Paso County, Colorado.

(105t) Limestone [Walcott, 1908f, p. 173] at the summit of Notch Peak, House Range, Millard County, Utah.

(185z) Limestones at the base of the Lower Ordovician [Walcott, 1908f, p. 191] in Blacksmith Fork Canyon, about 9 miles (14.4 km.) east of Hyrum, Cache County, Utah.

Passage beds between the Upper Cambrian and the Ordovician: (34g) Limestone about 1,000 feet (305 m.) above the valley on the east side of the Fish Spring Range, just west of the high point southwest of the J. J. Thomas ranch, Tooele County, Utah.

Upper Cambrian: (30w) Drift boulder of limestone supposed to have come from 1a of the Notch Peak limestone on Notch Peak [Walcott, 1908f, p. 175], found about 2 miles (3.2 km.) south of Marjum Pass, House Range [Walcott, 1908f, Pl. XIII], Millard County; (331) limestones in pass between the Pavant Mountains and the Canyon Range, a few hundred yards east of the divide, on the road between Holden and Scipio, Millard County; and (54r) drift pieces of limestone from the west slope of the Wasatch Range, east of the Lakeview ranch, about 5 miles (8 km.) north of Brigham, Boxelder County; all in Utah.

(54b) About 1,200 feet (365.8 m.) above the Middle Cambrian and 25 feet (7.6 m.) below the top of the Upper Cambrian in the upper part of the limestone forming 1 of the St. Charles formation [Walcott, 1908f, p. 191]; (54c) about 1,100 feet (335.3 m.) above the Middle Cambrian and 120 feet (36.6 m.) below the top of the Upper Cambrian, in the central part of the limestone forming 1 of the St. Charles formation [Walcott, 1908f, p. 192]; and (54d) about 1,050 feet (320 m.) above the Middle Cambrian and 175 feet (53.3 m.) below the top of the Upper Cambrian in the lower part of the limestone forming 1 of the St. Charles formation [Walcott, 1908f, p. 192]; all in Blacksmith Fork Canyon, about 10 miles (16.1 km.) east of Hyrum, Cache County, Utah.

(158) Limestones north of East Gallatin River, near Hillsdale; and (340b) limestone at the mouth of Fourmile Creek; both in the Threeforks quadrangle (U. S. Geol. Survey), Gallatin County, Montana.

(327) Arenaceous limestone east of Gold Camp, in the Caballos Mountains, New Mexico.

(14k) Limestone on Wolf Creek, 15 miles (24.2 km.) west-southwest of Sheridan, Bighorn Mountains; and (168) limestone on north side of Tepee Creek, beside the road from Sheridan to Dome Lake, Bighorn Mountains; both in Sheridan County, Wyoming.

(346b) Conococheague limestone, 2.75 miles (4.4 km.) south of Mercersburg, Franklin County, Pennsylvania.

Specimens that are somewhat doubtfully referred to this species occur at the following localities:

Upper Cambrian: (152) Limestone on ridge between Churn and Cottonwood Canyons, west side of Bridger Range; and (154) limestone in hill on west side of Dry Creek, opposite mouth of Pass Creek, about 5 miles (8 km.) north of Hillsdale, Threeforks quadrangle (U. S. Geol. Survey); both in Gallatin County, Montana.

Upper ? Cambrian: (306) Sandy limestone on Gravel River, eastern slope of the Rocky Mountains, in the Mackenzie River basin, British Columbia.

EOORTHIS DESMOPLEURA NYMPHA (Walcott).

Plate XCVI, figure 2.

Orthis (Plectorthis) desmopleura nympha WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 262. (Characterized as below as a new variety.)

This variety is based on strongly convex ventral valves in which the surface is marked by fine radiating striæ, separated into bands of 3 to 6 striæ by stronger and more elevated striæ. Some shells show concentric lines and often ridges of growth that give an imbricated appearance to the portion of the surface beyond the umbo.

FORMATION AND LOCALITY.—**Lower Ordovician:** (186) Near line of contact between red and gray Ordovician limestone, in red siliceous limestone about 30 feet (9.1 m.) above the pre-Cambrian rocks, Williams Canyon, Manitou, El Paso County, Colorado.

Upper Cambrian: (168) Limestone on north side of Tepee Creek, near the road from Sheridan to Dome Lake, Bighorn Mountains, northern Wyoming.

EOORTHIS ? DIABLO (Walcott).

Plate XCIII, figure 3.

Orthis (Plectorthis) diablo WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 262. (Described as below as a new species.)

This species is founded on a small, transverse shell that is marked by a few prominent radiating costæ that extend from the umbo to the margin of the shell. In the cast the costæ have a sharp summit and slope evenly to a narrow space between them.

A ventral valve 9 mm. in height has a width of 14 mm., which is about the average proportion of the specimens in the collection. The casts of the ventral valve show a rather low area divided by a delthyrium, the inner angles of which have a rather strong tooth. The dental plates extend backward farther than in most species of the genus, becoming attached to the bottom of the valve only near the teeth, and not extending forward as in *Eoorthis remnicha* to form a pseudospondylium. None of the specimens in the half dozen shells in the collection

show the muscular or vascular markings. There may or may not be a mesial depression on either valve. The reference of this species to *Eoorthis* is made with much reservation.

FORMATION AND LOCALITY.—Upper Cambrian: (81b) "St. Croix sandstone," near Devils Lake, Sauk County; and (83) "St. Croix sandstone," near Trempealeau, Trempealeau County; both in Wisconsin.

EOORTHIS DORIS (Walcott).

Plate XCVII, figures 13, 13a.

Orthis (*Plectorthis*) *doris* WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 262-263. (Described and discussed as below as a new species.)

Of this species a ventral and dorsal valve occur in the collection. General form rounded subquadrangular. Ventral valve strongly convex, with the greatest height at the umbo, from which the beak arches over a high backward-inclining area. Dorsal valve much like the ventral in form except that it is less convex and less elevated at the area.

Surface of both valves with numerous radiating ribs that have an angular summit and an angular depression between them. The ribs increase in number toward the front by interpolation. The ventral valve has a length of 7 mm.; width, 8 mm. The dorsal valve is a little shorter than the ventral.

Observations.—This shell is not unlike *Eoorthis indianola* in form and surface characters. It differs in being more convex and in the absence of a sinus or median fold on either valve.

FORMATION AND LOCALITY.—Upper Cambrian: (C64) Upper limestone member of the Kiulung group [Blackwelder, 1907a, pp. 37 and 42 (first list of fossils), and fig. 10 (bed 20), p. 38], 2.7 miles (4.3 km.) southwest of Yenchuang, Sintai district, Shantung, China.

EOORTHIS HASTINGSSENSIS (Walcott).

Plate XCIV, figures 3, 3a-c.

Orthis (*Plectorthis*) *hastingsensis* WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 263. (Described and discussed as below as a new species.)

Shell transversely subelliptical. Surface with numerous strong, rounded, radiating ribs increasing in number by interpolation; the ribs appear to be broader and with narrower interspaces on the ventral valve; concentric ridges and fine striæ of growth are a marked feature of the surface. A ventral valve 4 mm. in length has a width of 6 mm.; a dorsal valve 6 mm. long is 10 mm. in width.

Ventral valve strongly convex, most elevated on the umbo, and without mesial fold; apex incurved slightly over the delthyrium; area well defined, and divided midway by a large delthyrium; it is inclined but little from the vertical.

Dorsal valve slightly convex in young shells, and becoming more so as they increase in size; area low and inclined backward over the hinge line.

Observations.—This species is unlike other described forms in the character of its ribs, with the exception of *Eoorthis johannensis*, which it resembles very closely. Matthew [1892, p. 49] describes the latter species as having a very thin shell, and it is found in the Upper Cambrian at St. John. No interior features have been seen. Matthew [1897b, p. 170] mentions having found fragments of *Protorthis* or *Orthis* in the phosphate nodules at Hastings Cove, too imperfect for description.

The species derives its specific name from its occurrence at Hastings Cove.

FORMATION AND LOCALITY.—Middle Cambrian: (21 and 2m)^a Limestone and superjacent shale at the base of the *Paradoxides* zone [Matthew, 1895a, p. 108], on Hanford Brook, St. John County; and (2s) limestone in upper part of *Paradoxides* zone, Hastings Cove [Matthew, 1898b, p. 38], on Kennebecasis Bay, 0.5 mile (0.8 km.) northeast of Torryburn, on the Intercolonial Railway northeast of St. John, St. John County; all in New Brunswick.

^a 21 is the type locality.

EOORTHIS IDDINGSI (Walcott).

Plate XCI, figures 3, 3a-b.

Orthis? remnicha WALCOTT (in part) [not N. H. WINCHELL, 1899, Mon. U. S. Geol. Survey, vol. 32, pt. 2, pp. 451-452, Pl. LXII, figs. 1a and 1b (not Pl. LXI, figs. 3 and 3a, or Pl. LXII, figs. 1, 1c, and 1d). (Specimens now referred to *Eoorthis iddingsi* were included with *E. remnicha* when this description was written, two being figured, Pl. LXII, figs. 1a and 1b. The specimens represented by these two figures are redrawn in this monograph, Pl. XCI, figs. 3 and 3a, respectively. The specimens represented by Pl. LXI, figs. 3 and 3a, and Pl. LXII, figs. 1, 1c, and 1d belong with *Eoorthis remnicha*.)

Orthis (Plectorthis) iddingsi WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 264. (Characterized as below as a new species.)

General form and convexity much like that of some varieties of *Eoorthis indianola*. Its surface characters also approach those of the more regularly ribbed shells of the latter species. The principal difference between the two species is the less convexity, lower umbo, and lower area of *E. iddingsi*. The interior of the ventral valve shows a short, well-defined umbonal cavity with a strong vascular sinus on each side of it that extends well forward into the valve.

The specific name is given in honor of Prof. Joseph P. Iddings.

FORMATION AND LOCALITY.—Upper Cambrian: (302c) *Shaly limestone on the south side of the Gallatin Valley, Yellowstone National Park, Wyoming*; and (302d) limestone 200 yards (183 m.) north of the southwest corner sec. 18, T. 28 N., R. 113 W., Uinta County; both in Wyoming.

(71) Limestone in Cold Creek Canyon, Burnet County, Texas.

EOORTHIS INDIANOLA (Walcott).

Plate XCIV, figures 1t, 1u, 2, 2a-h.

Orthis (Plectorthis) indianola WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 264-265. (Described and discussed essentially as below, as a new species.)

Plectorthis indianola (Walcott), GRABAU and SHIMER, 1907, North American Index Fossils, vol. 1, pp. 251-252. (Described.)

Shell small, transverse, with the cardinal extremities rounded, angular, and in some specimens almost alate. Valves moderately convex, the ventral nearly twice as much so as the dorsal; the length of the hinge line varies from slightly less than the greatest width of the shell to one-fifth greater than the width of the shell across the center, in shells with extended cardinal extremities.

The ventral valve may or may not have a mesial depression. In some examples the depression is broad and rounded, and in others it is shallow with stronger ribs at each margin; umbo somewhat elevated, and curving over toward the hinge line, beyond which it projects, terminating in a small, incurved beak; dorsal valve considerably less convex than the ventral; beak small and projecting slightly over the hinge line. The median sinus in the dorsal valve varies from a broad, shallow depression to a narrow, rather deep, furrow, that gives a bilobed appearance to the valve (Pl. XCIV, fig. 2f).

The strength and arrangement of the strong and minor radiating elevated ribs and striae are quite variable. On some shells the ribs or striae are very fine, of nearly equal size, and separated by grooves of about the same width (Pl. XCIV, figs. 2f, 2g, and 2h). In other examples every third or more widely separated rib is stronger and elevated above a more or less broad interspace, marked by fine ribs or costae (Pl. XCIV, fig. 2). A few of the variations in surface are illustrated.

Almost nothing is known of the interior of the valves. Below the umbo in a few specimens there is a well-marked pseudospondylium that is much like that of *E. remnicha*. The area of the ventral valve is inclined at an angle of about 65° to the plane of the margin of the valve; it is rather low and broken midway by a strong delthyrium. The area of the dorsal valve is low and inclined well out over the hinge line.

Observations.—*Eoorthis indianola* is almost as variable in its form and surface markings as *E. wichitaensis*, with which it is associated at a number of localities. It differs from the latter in its bilobed dorsal valve, more strongly incurved umbo and apex of the ventral valve, and

the general appearance of convexity and rotundity of the ventral valve. This may be seen by comparing the shells marked W = *E. wichitaensis* with those marked X = *E. indianola* in Plate XCIV, figure 1u, which represents a fragment of limestone in which the two species are associated. When the specimens of the two species are imperfect or the young shells of *E. wichitaensis* occur in association with the shells of *E. indianola* it is difficult to determine positively to which species they belong.

The specific name is derived from Indian Territory (now Oklahoma), in which the type specimen was found.

FORMATION AND LOCALITY.—Upper Cambrian: (369) Sandstones at the base of the Elvins formation, in the eastern limits of the town of Flat River, St. Francois County; and (369b) limestone near Potosi, Washington County; both in Missouri.

(9t) About 170 feet (52 m.) above the porphyry contact in the limestones of the Reagan sandstone; and (9u) about 195 feet (59.4 m.) above the porphyry contact in the limestones of the Reagan sandstone; both in the SE. $\frac{1}{4}$ NE. $\frac{1}{4}$ sec. 2, T. 4 N., R. 13 W., about 15 miles (24.2 km.) northwest of Fort Sill, Comanche County, Oklahoma.

(9w) About 100 feet (30.5 m.) below the Arbuckle limestone, in the limestones of the Reagan sandstone, SW. $\frac{1}{4}$ sec. 17, T. 4 N., R. 12 W., about 11 miles (17.6 km.) northwest of Fort Sill, Comanche County, Oklahoma.

(12k) Limestones of the Reagan sandstone (in the section 7 miles (11.2 km.) north of Springer this horizon is about 225 feet (69 m.) above the porphyry contact and 55 feet (17 m.) below the Arbuckle limestone), on the west side of Honey Creek, near the southeast corner of sec. 35, T. 1 S., R. 1 E., Ardmore quadrangle (U. S. Geol. Survey), Carter County; (12n) limestones of the Reagan sandstone (in the section 7 miles (11.2 km.) north of Springer this horizon is about 240 feet (73 m.) above the porphyry contact and 40 feet (12 m.) below the Arbuckle limestone), NW. $\frac{1}{4}$ sec. 1, T. 2 S., R. 1 E., Ardmore quadrangle (U. S. Geol. Survey), Carter County; and (12p) about 225 feet (69 m.) above the igneous rocks in the limestones of the Reagan sandstone, at the northwest extremity of the Arbuckle Mountains, about 4 miles (6.4 km.) east of Homer, Carter County; all in Oklahoma.

(14b) Limestone on Cold Creek at north end of gorge opposite the north end of Sponge Mountain, 2 miles (3.2 km.) south of the San Saba County line, in Llano County; and (71) limestone in Cold Creek Canyon, Burnet County; all in Texas.

Specimens that are doubtfully referred to this species occur at the following locality:

Upper Cambrian: (68) Limestone on Packsaddle Mountain, Llano County, Texas.

EOORTHIS JOHANNENSIS (Matthew).

Plate XCVII, figures 10, 10a.

Orthisina(?) *johannensis* MATTHEW, 1892, Trans. Roy. Soc. Canada for 1891, 1st ser., vol. 9, sec. 4, No. 5, pp. 49–50, Pl. XII, figs. 13a–c. (Described and discussed as a new species; see below for copy. The specimens represented by figs. 13a–c are redrawn in this monograph, Pl. XCVII, figs. 10 and 10a, respectively.)

Orthis (*Plectorthis*) *johannensis* (Matthew), WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 265–266. (Original description copied and species discussed as below.)

The original description by Matthew follows:

Shell subquadrate, doubly convex, rather flat, very thin.

Dorsal valve depressed at the sides and front, and having a broad, shallow median sinus. The valve is about one-quarter wider than long, and the hinge line is nearly as long as the length of the shell. Umbo slightly elevated, hinge plate weak and thin.

Ventral valve depressed at the sides, and having a few median ridges running from the umbo to the front of the shell. This valve is somewhat geniculated at two-fifths of its length from the umbo, and from the bend faintly raised ridges diverge to the anterior angles of the shell; behind the geniculation the surface of the shell is marked by faint undulations similar to those of *Strophomena rhomboidalis*.

The umbo is not prominent, but the back of the valve is regularly curved and the area rather low.

Closely set striae radiating from the umbo and faint concentric striae mark the shell.

Length of the ventral valve, 9 mm.; width, 10 mm. Length of dorsal, 8 mm.; width, 10 mm.

This species has a low umbo for an *Orthisina*, and in its form recalls the genus *Strophomena*, as also do the concentric undulations that are found on the back of the ventral valve. The dorsal valve, however, is convex, and the area of this and the ventral valve too high for a *Strophomena*. It does not appear to agree with any described species of *Orthisina*. It resembles *O. orientalis* White somewhat in form, but is not so long nor so wide at the hinge. From *O. pepina* Hall it differs in its lower umbo and area, shorter hinge, and smoother surface. It approaches more closely to the form from the Potsdam sandstone of the West, figured by Hall [1863, Pl. VI, fig. 22], but not named, except as "*Strophomena* or *Strophodonta*."

Doctor Matthew very kindly sent me the types of this species. There is little that can be added to his very complete description, but I had two enlarged drawings made to illustrate

the character of the surface more fully than the illustrations given by Matthew [1892, Pl. XII, figs. 13a-c]. As far as known, the characters of the shell are those of the group of species referred to *Eoorthis*.

FORMATION AND LOCALITY.—Upper Cambrian: (308b [Matthew, 1892, p. 49]) Limestone lentiles in black shales of Division C3a of Matthew's section, Germaine Street, St. John, St. John County, New Brunswick.

EOORTHIS KAYSERI (Walcott).

Plate XCVII, figures 6, 6a-b.

Orthis (Plectorthis) kayseri WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 266. (Characterized as below as a new species.)

This is a larger shell than *Eoorthis linnarssoni* (Kayser), with which it is associated. Its surface is marked by numerous fine radiating striæ, four or five in a distance of 1 millimeter, and the inner layers of the shell appear to be minutely punctate. The ventral valve is more convex than the dorsal, the latter being nearly flat in young shells. Nothing is known of the interior, except one cast of the pseudospondylium of the dorsal valve, which is larger in proportion than that of *E. linnarssoni*.

The largest ventral valve has a length of 14 mm.; width, 20 mm.

This species belongs in the group of *Eoorthis* represented by *E. desmopleura* (Meek) and *E. linnarssoni* (Kayser).

The specific name was given in honor of Dr. E. Kayser.

FORMATION AND LOCALITY.—Upper Cambrian: (C64) Upper limestone member of the Kiulung group [Blackwelder, 1907a, pp. 37 and 42 (first list of fossils), and fig. 10 (bcd 20), p. 38], 2.7 miles (4.3 km.) southwest of Yenchuang, Sintai district, Shantung; (C68) upper part of the Chaumitien limestone [Blackwelder, 1907a, p. 36 (part of third list of fossils)], at Chaumitien, Changhia district, Shantung; and (C74) a dense blue dolomitic limestone at the top of the Kichou limestones [Willis and Blackwelder, 1907, pp. 139 and 145 (5th list of fossils)], 4 miles (6.4 km.) east of Fanglanchon, Shansi; all in China.

EOORTHIS KICHOUENSIS (Walcott).

Plate LXXXIX, figure 5.

Orthis (Plectorthis) kichouensis WALCOTT, 1906, Proc. U. S. Nat. Mus., vol. 30, p. 570. (Described as below as a new species.)

This species is represented by one specimen of the dorsal valve. The outline of the shell is transversely rounded subquadrilateral; length, 9 mm.; width, 13 mm.; the highest point above the plane of the margin is about 3 mm.; the shallow median sinus, which begins at the umbo above the hinge line, gradually widens toward the front margin; the umbo curves over beyond the hinge line and then under to the beak, which apparently is at or a little over the upper edge of a very narrow area.

Surface marked by numerous radiating, rounded ribs, with narrow interspaces, 7 ribs in a distance of 45 mm.; a few bifurcations of the ribs occur at irregular intervals between the apex and the margins. There are no traces of concentric striæ; if on the shell originally, they have been removed by the wearing off of the outer surface.

Observations.—This species is distinguished from all other species by the strong, incurved umbo and rounded ribs with narrow interspaces.

The specific name was derived from the Kichou formation, in which the species occurs.

FORMATION AND LOCALITY.—Middle Cambrian: (C75) Limestone near the base of Kichou formation [Willis and Blackwelder, 1907, p. 143], 4.5 miles (7.2 km.) south of Wutaihien, Shansi, China.

EOORTHIS LINNARSSONI (Kayser).

Plate XCVII, figures 5 and 5a.

Orthis linnarssoni KAYSER, 1883, China, by Richthofen, vol. 4, p. 34, Pl. III, fig. 1. (Described and discussed in German as a new species, see p. 783 for translation. Fig. 1 is reproduced in this monograph, Pl. XCVII, fig. 5a.)

Orthis (Plectorthis) linnarssoni (Kayser), WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 266. (Original description copied and species discussed as below.)

The original description by Kayser follows:

Shell semielliptical in outline, broader than long, with hinge edge straight, corresponding to the greatest breadth of the shell. Large (ventral) valve moderately convex. Small (dorsal) valve slightly arched, with a sinus which develops at the umbo and grows quite broad and deep toward the edge. Umbo of ventral valve small, area very low. Surface of shell covered with rather sharp ribs, exceedingly variable in strength, separated by narrow furrows. By reason of repeated splitting, which begins close to the umbo, the ribs appear more like bundles of ribs. On the matrix these bundles appear as broad, obtuse-angled folds, which, owing to repeated marginal splitting in even a higher degree than on the shell itself, appear as bundles of ribs of very unlike strength. When the surface is well preserved, a delicate concentric growth striation is perceptible.

Kayser [1883, p. 35] compares this shell with "*Orthis hicksi*" Salter and "*O. exporrecta*" Linnarsson, on account of the surface characters. It does not appear to be very closely related to either species, but it is in many respects allied to *Eoorthis desmopleura* (Meek) and *E. wichitaensis* (Walcott).

The specific name is given in honor of Dr. J. G. O. Linnarsson.

FORMATION AND LOCALITY.—Upper Cambrian: (C64) Upper limestone member of the Kiulung group [Blackwelder, 1907a, pp. 37 and 42 (first list of fossils), and fig. 10 (bed 20), p. 38], 2.7 miles (4.3 km.) southwest of Yenchuang, Sintai district; and (C67) stream gravels used in making the railroad grade 0.33 mile (0.5 km.) west of the west city gate at Tsinan; both in Shantung, China.

(332a) [Kayser, 1883, p. 34] Taling, Liaotung, China.

EOORTHIS NEWBERRYI Walcott.

Text figures 69A-D.

Eoorthis newberryi WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 3, p. 105, Pl. X, figs. 6 and 6a. (Described and discussed as below as a new species. Figs. 6 and 6a are copied in this monograph as figs. 69B and 69D.)

Shell transversely subelliptical, with the cardinal extremities obtusely angular; valves moderately convex, with the hinge line a little shorter than the greatest width of the valves. The only ventral valve in the collection showing a mesial fold (fig. 69A) is a small exfoliated shell that is somewhat doubtfully referred to the species. Two large valves, one of which is illustrated by figure 69B, have the posterior margin extended beyond the hinge line, with a short incurved beak; a broad, shallow median sinus begins in front of the umbo and widens to nearly one-third of the width of the valve at the frontal margin. On a shell 5 mm. in length the sinus is very shallow; area unknown. The dorsal valve is almost uniformly convex and without a mesial sinus or fold; the front margin arches upward a little to provide for the extension of the margin of the ventral valve caused by its broad median sinus; beak minute and marginal; area unknown.

Surface marked by concentric lines and ridges of growth and small, rounded, radiating ribs, with two or three smaller ribs between each two larger ridges. The shell structure is fibrous and impunctate as far as can be determined from the material available for study. The largest ventral valve has a length of 14 mm.; width, 18 mm. A dorsal valve 15 mm. in length has a width of 18 mm.

Observations.—In form this species resembles some species of *Eoorthis remnicha* (Winchell) (Pls. XCI, XCII), but in surface characters it is quite unlike any of them.

FIGURE 69.—*Eoorthis newberryi* Walcott. A, Partly exfoliated ventral valve (U. S. Nat. Mus. Cat. No. 52350a). B, Ventral valve, the type specimen, preserving some of the surface characters (U. S. Nat. Mus. Cat. No. 52350b). C, Small exfoliated ventral valve (U. S. Nat. Mus. Cat. No. 52350c). D, Partly exfoliated dorsal valve (U. S. Nat. Mus. Cat. No. 52350d).

The specimens represented are from Locality 54c, Upper Cambrian limestone of the St. Charles formation, in Blacksmith Fork Canyon, east of Hyrum, Cache County, Utah. Figures 69B and 69D are copied from Walcott [1908d, Pl. X, figs. 6 and 6a].

The specific name is given in honor of Dr. J. S. Newberry.

FORMATION AND LOCALITY.—Upper Cambrian: (54c) About 1,100 feet (335.3 m.) above the Middle Cambrian and 120 feet (36.6 m.) below the top of the Upper Cambrian in the central part of the limestones forming 1 of the St. Charles formation [Walcott, 1908f, p. 192]; and (54d) about 1,050 feet (320 m.) above the Middle Cambrian and 175 feet (53.3 m.) below the top of the Upper Cambrian, in the lower part of the limestones forming 1 of the St. Charles formation [Walcott, 1908f, p. 192]; both in Blacksmith Fork Canyon, about 10 miles (16.1 km.) east of Hyrum, Cache County, Utah.

EOORTHIS NEWTONENSIS (Weller).

Plate XCVII, figures 9, 9a.

Orthis newtonensis WELLER, 1903, Geol. Survey New Jersey, Rept. Paleontology, vol. 3, pp. 113–114, Pl. I, figs. 3–5. (Described and discussed as a new species.)

Orthis (Plectorthis) newtonensis (Weller), WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 267. (Described and discussed as below.)

- This little shell occurs in the form of casts in a sandstone that is too coarse to preserve the details of the outer surface. The cast of the interior shows fine, simple, radiating ribs that increase by interpolation and that are coarser on the ventral than on the dorsal valve. Ventral valve slightly flattened at the front; dorsal valve with a broad mesial sinus. The shell appears to have been thin. The cast of the pseudospondylium of the ventral valve shows it to have been clearly defined; the area is low and not sharply defined from the curve of the cardinal margin; it is nearly vertical to the plane of the margin of the valve. The cast of the area beneath the umbo in the dorsal valve is more triangular and less transverse than usual; unfortunately the material is too imperfect to determine any details.

Observations.—This species is the eastern representative in the Upper Cambrian of *Eoorthis indianola* (Walcott) and *E. iddingsi* (Walcott). As far as can be determined by the material available for comparison it is closely related to those species but it is not probable that they are specifically identical.

The specific name is derived from Newton, New Jersey.

FORMATION AND LOCALITY.—Upper Cambrian: (11c) Hardyston quartzite [Weller, 1900, pp. 10 and 12], O'Donnell and McManniman's quarry, Newton, Sussex County, New Jersey.

EOORTHIS PAGODA (Walcott).

Plate XCVII, figures 12, 12a–d.

Orthis (Plectorthis) pagoda WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 267–268. (Described and discussed as below as a new species.)

Shell transverse, subsemicircular; a ventral valve 11 mm. in length has a width of 15 mm., and a dorsal valve 8 mm. in length has a width of 13 mm.; hinge line a little shorter than the greatest width of the shell; cardinal angles vary from 75° to 111°; valves moderately convex. Cardinal area narrow in both valves and inclined backward from the hinge line. Surface marked by equidistant, narrow, low ribs, 3 in a space of 2 mm. near the front margin of a shell 10 mm. long, with fine, radiating striæ between them; the radiating ribs and striæ are crossed by fine, concentric striæ, and lines of growth.

Ventral valve with a strong, somewhat angular, median fold rising from a well-defined depression on each side of it, or it might be designated as a very strong rib rising above the general surface of the valve from a broad, median depression; the lateral slopes are gently convex. Dorsal valve with a strong, angular, median depression, beginning at the posterior margin and gradually widening to the front; the sides of the depression rise above the general surface of the valve, and form with the outer slope a well-defined low ridge on each side that extends a little forward on the front margin to fit into the depressions on each side of the median fold of the ventral valve.

The interior of a small dorsal valve has a broad, strong ridge corresponding to the depression on the exterior surface; a main vascular sinus starts on each side of the base of the median ridge and arches outward and then forward about a depressed oval space on each side of the

ridge; lateral branches extend from the main sinus toward the sides; the impressions of the anterior and posterior adductor muscle scars occur on the slopes of the median ridge and the oval depressions; somewhat obscure radiating lines mark the anterior portions of the surface.

Observations.—This shell is distinguished by its strongly marked median ridge on the ventral valve and sinus on the dorsal valve. In general form and surface markings it is not unlike *Eoorthis desmopleura* (Meek) and *E. wichitaensis* (Walcott).

The specific name is derived from Pagoda Hill, the type locality.

FORMATION AND LOCALITY.—Upper Cambrian: (C56) Lower part of Chaumitien limestone, at Pagoda Hill [Blackwelder, 1907a, p. 42 (part of last list of fossils)], 1 mile (1.6 km.) west of Tsinan; and (C54) lower part of the Chaumitien limestone [Blackwelder, 1907a, p. 42 (part of last list of fossils)], 0.66 mile (1.1 km.) west of Tsinan; both in Shantung, China.

EOORTHIS PAPIAS (Walcott).

Plate XCI, figure 4.

Orthis (Plectorthis) papias WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 268. (Characterized as below as a new species.)

This species is founded to receive a form represented by two small dorsal valves from the *Paradoxides* zone of Newfoundland. They are moderately convex, with a low area divided by a broad delthyrium; surface marked by numerous, rounded, depressed ribs, crossed by concentric striæ and ridges of growth. Length of shell, 4 mm.; width, 5 mm.

FORMATION AND LOCALITY.—Middle Cambrian: (61) Shales near the top of No. 6 of the Manuels Brook section [Walcott, 1891b, p. 261], east side of Manuels Brook, Conception Bay, Newfoundland.

EOORTHIS PRIMORDIALIS (de Verneuil and Barrande).

Plate XCVII, figures 1, 1a-d.

Orthis primordialis DE VERNEUIL and BARRANDE, 1860, Bull. Soc. géol. France, 2d ser., vol. 17, pp. 532-533, Pl. VIII, figs. 6, 6a-d. (Described and discussed in French, as a new species; see below for translation. Figs. 6, 6a-d are reproduced in this monograph, Pl. XCVII, figs. 1, 1a-d, respectively.)

Orthis primordialis de Verneuil and Barrande, MALLADA, 1875, Bol. Com. Mapa Geológico España, tome 2, p. 31. (Mentioned in Spanish.)

The original description by de Verneuil and Barrande follows:

Shell transverse, rounded on the sides, wider than long. Hinge ridge does not extend to lateral extremities and measures hardly more than three-fourths of the total breadth of the shell. The two valves are of about the same thickness. The ventral valve^a is provided with an area hardly higher than that of the opposite valve, but it is distinguished from it by a sinus which is almost as deep as that of the Spirifers, and which in front forms a very pronounced and more or less sharp fold. Surface ornamented with striæ, very dichotomous on the sides and almost simple in the sinus; at a distance of 5 mm. from the beak, 7 striæ are counted in a space of 5 mm.

Breadth, 16 mm.; length, 12 mm.; thickness, 7 mm.

By its deep sinus, this species is distinguished from most of its congeners and establishes a sort of passage between the genera *Orthis* and *Spirifer*; however, the pronounced area observed on each of the two valves is a characteristic which links it with the former rather than with the latter genus. *Orthis* species provided with sinuses are rather rare; the principal ones are *O. sinuata* Hall and *O. striatula* Schl., which for that matter have no other analogy with our species. It might perhaps be assimilated to *O. lynx*, which also has two areas equally developed, but the latter species will always be recognized by the small number and nondichotomous nature of its folds.

Observations.—This shell is more strongly developed in the sinus of the ventral valve and the fold of the dorsal valve than any other species of Cambrian *Eoorthis*, with the possible exception of *E. indianola* (Walcott) of the Middle and Upper Cambrian of the Wichita Mountains of the United States. The latter has a higher area on the ventral valve and the sinus is often shallow, while the fold is usually absent.

FORMATION AND LOCALITY.—Middle Cambrian: (350 [de Verneuil and Barrande, 1860, p. 538]) Red limestone of the *Paradoxides* zone, near Adrados, north of Sabero and Boñar, Cantabrian Mountains, Province of Leon, northwestern Spain.

^a Following here the example of Owen and Davidson, we call ventral valve the larger of the two, the one which is provided with a large area, and which formerly was called dorsal valve.

EOORTHIS REMNICA (N. H. Winchell).

Text figure 7, page 299; Plate XCI, figures 1, 1a-s; Plate XCII, figures 2, 2a-d, 3, 3a-e.

- Orthis remnica* N. H. WINCHELL, 1886, Fourteenth Ann. Rept. Geol. and Nat. Hist. Survey Minnesota, pp. 317-318, Pl. II, fig. 7. (Described and discussed as a new species.)
- Orthis? remnica* Winchell, WALCOTT (in part), 1899, Mon. U. S. Geol. Survey, vol. 32, pt. 2, pp. 451-452, Pl. LXI, figs. 3 and 3a; Pl. LXII, figs. 1, 1c-d (not figs. 1a and 1b). (Described and discussed essentially as below. The specimens represented by Pl. LXI, figs. 3 and 3a, and Pl. LXII, figs. 1, 1c, and 1d, are redrawn in this monograph, Pl. XCII, figs. 2b, 2a, 2, 2d, and 2c, respectively. The specimens represented by Pl. LXII, figs. 1a and 1b, are now referred to *Eoorthis iddingsi*.)
- Orthis (Plectorthis) remnica* (Winchell), WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 268-269. (Described and discussed essentially as below.)
- Plectorthis remnica* (Winchell), GRABAU and SHIMER, 1907, North American Index Fossils, vol. 1, p. 252. (Described.)

Shell of medium size, usually slightly transverse, with an oblong, oval outline for the ventral valve, and a subquadrate to semicircular outline for the dorsal valve. Valves moderately convex, with an almost straight hinge line that varies in length from nearly the greatest width of the shell to two-thirds the greatest width; cardinal angles varying from 90° or less in the extreme forms, with extremities somewhat angular, to the other extreme, where they are very obtuse and have the appearance of being almost rounded, their angle being not less than 120°. Cardinal area narrow but well developed on each valve, and divided by a rather large delthyrium.

The ventral valve has in some specimens a shallow mesial depression, and in some examples it is flattened toward the cardinal angles; beak small and curving down toward the hinge line, beyond which it projects slightly. Dorsal valve slightly less convex than the ventral; beak small, scarcely projecting beyond the hinge line.

Surface marked by bifurcating, radiating costæ, that vary in number on shells of similar size from 16 in the space of 5 mm. to 3 in the same space; this variation is shown in the specimens from Texas, Wisconsin, and Wyoming. As the shell grew the ribs increased in number by interpolation and by bifurcation from the sides of the larger ribs. In well-preserved specimens very fine, radiating, raised striæ occur both on the costæ and on the intervening depressions (Pl. XCII, fig. 2c). These are shown on the casts of the shells from the "St. Croix sandstone of Winfield, Wisconsin, and on the larger shells from the limestones of Oklahoma and the Yellowstone National Park. A very perfectly preserved fragment of the outer shell covering the umbo and apex of a ventral valve from the limestone of the Reagan sandstone, Oklahoma, has sharp ribs of varying size extending to the worn apex; the ribs are crossed by very fine, threadlike striæ and a few stronger lines of growth.

The interior of the ventral valve shows a slightly raised tripartite pseudospondylium beneath the umbo, which is the only trace of interior markings of this valve observed. The interior of the dorsal valve has a slightly elevated area upon which occurs a narrow, short median septum; the crural plates are also well shown. In casts of the interior of shells from the "St. Croix sandstone" of Wisconsin, the dental lamellæ of the ventral valve are finely shown, and in the dorsal valve the median septum and crural plates.

Observations.—The shell is one of the most variable that occurs in the Cambrian fauna. Its range of variation in all of the widely separated localities in which it occurs is such that one would scarcely hesitate, if in possession only of the extremes, to identify two well-marked species. The variation is not only in the radiating costæ, but also in the general form of the shell. This variation is expressed in three varieties that receive names, and others might be designated if more minute variations were given consideration.

There does not appear to be any system governing the number or size of the radiating ribs; the variation on adult shells is equally great with that between young shells 3 to 4 mm. long and adults. A series from Winfield, Wisconsin, representing *Eoorthis remnica winfieldensis*, is uniform in radial ribs and form from young shells 3 mm. long to the largest adults 23 mm. long, and there are also shells that serve to unite the numerous and uniformly ribbed specimens with the more variable *Eoorthis remnica*.

Some of the shells referred to *E. remnicha* (Pl. XCI, figs. 1, 1a, and 1e) suggest *Platystrophia* in their form and radiating ribs.

FORMATION AND LOCALITY.—**Upper Cambrian:** (80a) "St. Croix sandstone," 4 miles (6.4 km.) north of Reedsburg, Sauk County; (328q) "St. Croix sandstone" in quarry at Ableman, Sauk County; and (97a) "St. Croix sandstone," near Winfield, Jefferson County; all in Wisconsin.

(86a) "St. Croix sandstone," near Red Wing, Goodhue County, Minnesota.^a

(153a and 154) Limestone on west side of Dry Creek, near the mouth of Pass Creek, about 5 miles (8 km.) north of Hillsdale, Threeforks quadrangle (U. S. Geol. Survey), Gallatin County; (302n) limestone on the south side of the Gallatin Valley; Gallatin County; and (4r) just above the Middle Cambrian in the limestones of the Gallatin formation of Peale [1893, Pl. IV], on ridge 8 miles (12.8 km.) east of Yellowstone River, and 3 miles (4.8 km.) north-northeast of Mount Delano, Livingston quadrangle (U. S. Geol. Survey), Park County; both in Montana.

(168) Limestone on north side of Tepee Creek, beside the road from Sheridan to Dome Lake, Bighorn Mountains, Sheridan County, Wyoming.

(12k) Limestones of the Reagan sandstone (in the section 7 miles (11.2 km.) north of Springer this horizon is about 225 feet (69 m.) above the porphyry contact and 55 feet (17 m.) below the Arbuckle limestone) on the west side of Honey Creek, near the southeast corner of sec. 35, T. 1 S., R. 1 E., Ardmore quadrangle (U. S. Geol. Survey), Carter County; (12n) limestones of the Reagan sandstone (in the section 7 miles (11.2 km.) north of Springer this horizon is about 240 feet (73 m.) above the porphyry contact and 40 feet (12 m.) below the Arbuckle limestone), NW. $\frac{1}{4}$ sec. 1, T. 2 S., R. 1 E., Ardmore quadrangle (U. S. Geol. Survey), Carter County; and (12p) about 225 feet (69 m.) above the igneous rocks in the limestones of the Reagan sandstone, at the northwest extremity of the Arbuckle Mountains, about 4 miles (6.4 km.) east of Homer, Carter County; all in Oklahoma.

Middle Cambrian: (302b) Limestone near Crowfoot Ridge, Gallatin quadrangle (U. S. Geol. Survey), Yellowstone National Park, Wyoming.

Specimens that are somewhat doubtfully referred to this species occur at the following locality:

Middle Cambrian: (3x) About 2,200 feet (670.6 m.) above the Lower Cambrian and 2,200 feet (670.6 m.) below the Upper Cambrian in the limestone forming 1d of the Marjum limestone [Walcott, 1908f, p. 180], 2.5 miles (4 km.) east of Antelope Springs, in ridge east of Wheeler Amphitheater [Walcott, 1908f, Pls. XIII and XV], House Range, Millard County, Utah.

EOORTHIS REMNICHA SULCATA (Walcott).

Plate XCII, figures 1, 1a-c.

Orthis (*Plectorthis*) *remnicha sulcata* WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 269. (Characterized somewhat as below as a new variety.)

This variety is founded on the strongly sulcate dorsal valve. The ventral valve shows only a slight flattening of the median portion. *Finkelnburgia osceola* (Pl. XCIII) has a mesial fold on the dorsal valve, but it is not so sharp.

FORMATION AND LOCALITY.—**Upper Cambrian:** (80a) "St. Croix sandstone," 4 miles (6.4 km.) north of Reedsburg, Sauk County; and (97a) "St. Croix sandstone" near Winfield, Jefferson County; both in Wisconsin.

(339d) "St. Croix sandstone" at Taylors Falls, Chisago County; and (97x) "St. Croix sandstone" at Reads Landing, foot of Lake Pepin, Wabasha County; both in Minnesota.

EOORTHIS REMNICHA TEXANA (Walcott).

Plate XCII, figures 4, 4a-g.

Orthis (*Plectorthis*) *remnicha texana* WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 270. (Characterized as below as a new variety.)

The rounded, subquadrate form and the arrangement of the radiating costæ serve to differentiate this variety. The costæ vary considerably on different shells, but the tendency of the larger number is toward the surface represented by Plate XCII, figures 4c-g. Fine radiating striæ, similar to those represented by Plate XCII, figure 2c, of *Eoorthis remnicha* occur on the ribs and interspaces.

FORMATION AND LOCALITY.—**Upper Cambrian:** (12m) Arbuckle limestone (in the section 7 miles (11.2 km.) north of Springer this horizon is about 30 feet (9.1 m.) above the Reagan sandstone), NE. $\frac{1}{4}$ sec. 2, T. 2 S., R. 1 E.; and (12n) limestones of the Reagan sandstone (in the section 7 miles (11.2 km.) north of Springer this horizon is about 240 feet

^a N. H. Winchell [1886, p. 317] gives the type locality as "St. Croix sandstone" in sewer excavation at the corner of Brush and Main streets, Red Wing, Minnesota.

(73 m.) above the porphyry contact and 40 feet (12 m.) below the Arbuckle limestone), NW. $\frac{1}{4}$ sec. 1, T. 2 S., R. 1 E.; both in the Ardmore quadrangle (U. S. Geol. Survey), Carter County, Oklahoma.

(153a) Limestone in ravine on west side of Dry Creek, near the mouth of Pass Creek, about 5 miles (8.1 km.) north of Hillsdale, Threeforks quadrangle (U. S. Geol. Survey), Gallatin County, Montana.

(14b) Limestone on Cold Creek at north end of gorge opposite the north end of Sponge Mountain, 2 miles (3.2 km.) south of the San Saba County line, in Llano County; (68) interbedded sandstone and limestone, Packsaddle Mountain, Llano County; and (71) limestone in Cold Creek Canyon, Burnet County; all in Texas.

Specimens that are somewhat doubtfully referred to this variety occur at the following localities:

Upper Cambrian: (11d) Arenaceous limestone about 2 miles (3.2 km.) north of Montana, in sec. 22, T. 35 N., R. 1 E., Iron County; and (111) arenaceous limestone of the Elvins formation, 50 feet (15.2 m.) above the "Edgewise beds," St. Francois County; both in Missouri.

EOORTHIS REMNICHIA WINFIELDENSIS (Walcott).

Plate XCI, figures 2, 2a-e.

Orthis (Plectorthis) remnicha winfieldensis WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 270. (Characterized as below as a new variety.)

This variety is characterized by having finer and more uniform costæ than any of the shells referred to *Eoorthis remnicha* (N. H. Winchell). The costæ increase by interpolation rather than bifurcation in the true sense of the word. The shorter costæ begin as very narrow, sharp ridges, merging into the sides of the larger costæ below the summit of the latter, or they may arise entirely on the interspaces between the costæ. The pseudospondylium is less strongly developed than in *E. remnicha*. The young shells are usually narrower at the hinge line than the adult; but this feature is sometimes present in large shells (Pl. XCI, fig. 2c).

The varietal name is derived from Winfield, Wisconsin.

FORMATION AND LOCALITY.—**Upper Cambrian:** (97a) "St. Croix sandstone," near Winfield, Jefferson County; and (99a) "St. Croix sandstone" near Pilot Knob, Adams County; both in Wisconsin.

A specimen which is somewhat doubtfully referred to this variety occurs in the following locality:

Upper Cambrian: (83) "St. Croix sandstone" at Trempealeau, Trempealeau County, Wisconsin.

EOORTHIS SALTENSIS (Kayser).

Plate XCVII, figure 11.

Orthis saltensis KAYSER, 1876, Beiträge zur Geologie und Paleontologie der argentinischen Republik, vol. 2, Paleontologischen Theil; Abth. 1, p. 8, Pl. I, figs. 15, 16. (Described and discussed in German as a new species; see below for translation. Figs. 15 and 16 are reproduced in this monograph, Pl. XCVII, figs. 11' and 11, respectively.)

Orthis saltensis? KAYSER, 1897, Zeitschr. Deutsch. geol. Gesell. for 1897, Bd. 49, Heft 2, No. 2, p. 280. (Mentioned in German from new localities.)

Orthis (Plectorthis) saltensis (Kayser), WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 271. (Characterized.)

The original description by Kayser follows:

Shell nearly circular in outline, with straight hinge edge, which is about equal to three-fourths of the greatest breadth of the shell, measured approximately across the middle. Ventral valve moderately and uniformly arched, with a faint keel rising in the middle. Beak short, slightly curved. Dorsal valve slightly arched, with a median depression which is flat but becomes rather broad, starting at the umbo. The surface of both valves is covered with fine but plainly marked ribs, united into bundles, the lateral ones bending somewhat outward.

In the sandstones in the province of Salta this species fills whole beds. At the town of Salta it occurs alone. At the Nevada de Castillo it is accompanied by *Lingula*. At both localities it occurs as impressions and casts, and as white, well-preserved shell, peeling off in flakes. Finally it also occurs, associated with trilobites, *Hyalithes*, and other *Orthis* species, at Tilcuya in the province of Jujuy, but there it is without calcareous shell. I know only one primordial *Orthis* with which this fine species might be compared, namely *Orthis menapia* Hicks [cf. Davidson, 1869, Pl. XXXIII, figs. 8-12], from the English Arenig group. In this, however, the ribs show less tendency to arrange themselves in bundles, the sinus is narrower, and the ventral valve is much more strongly keeled.

Kayser's description and figures [1876, p. 8, Pl. I, figs. 15-16] lead me to refer this species to the genus *Eoorthis*. The general form of the valves, the casts of the interior of the ventral

valve with the strong umbonal cavity, and the radiating ribs increasing in number by interpolation, appear to sustain the reference.

The species derives its name from its occurrence near Salta.

FORMATION AND LOCALITY.—Upper Cambrian: (389 [Kayser, 1876, p. 8]) Sandstone at Salta, Province of Salta; (389a [Kayser, 1876, p. 8]) sandstone at Nevado de Castillo, Province of Salta; (389d [Kayser, 1897, p. 280]) at Iruya, Province of Salta; (389e [Kayser, 1897, p. 280]) in conglomeratic sandstone at Ojo de Agua, Province of Santiago del Est; and (389b [Kayser, 1876, p. 8]) sandstone at Tilcuya, Province of Jujuy; all in Argentina, South America.

Kayser [1876, p. 9, Pl. I, fig. 13] also describes and illustrates the dorsal valve of a shell that he refers to *Orthis* sp. It suggests *Orusia lenticularis*.

EOORTHIS TATEI (Etheridge).

Plate XCVII, figures 15 and 15a.

Orthis (?)*tatei* ETHERIDGE, JR., 1905, Trans. Roy. Soc. South Australia, vol. 29, p. 249, Pl. XXV, figs. 7 and 8. (Described as below, and discussed as a new species. The specimens represented by figs. 7 and 8 are redrawn in this monograph, Pl. XCVII, figs. 15 and 15a, respectively.)

The original description by Etheridge follows:

Pedicle valve, dorsal margin comparatively straight; ventral and lateral margins rounded, the former nonmarginate; umbo small, depressed; surface in the median line moderately convex, the wings rather flattened; sculpture consisting of numerous, thick, sometimes bifurcating radiating costæ, which die out, or are only faintly perceptible on the wings or toward the lateral margins of the valves, the surface on these portions being also crossed by very fine concentric lines; by the prominence of two or three costæ on each side of the middle, a flattened space, taking the place of a sulcus, is marked off.

This species appears to belong to the group of *Eoorthis* represented by *E. remnicha* (N. H. Winchell).

The specific name is given in honor of Mr. Ralph Tate.

FORMATION AND LOCALITY.—Middle? Cambrian: (315b [Etheridge, 1905, p. 249]) Limestone at Wirrialpa, Flinders Range, South Australia.

EOORTHIS THYONE Walcott.

Text figures 70A-C.

Nisusia rara WALCOTT (in part), 1908, Smithsonian Misc. Coll., vol. 53, No. 3, p. 97, Pl. IX, fig. 13 (not fig. 13a, which represents a specimen of *Nisusia rara*). (No text reference. Fig. 13, which is reproduced in this monograph as fig. 70A, was inserted on Pl. IX of this reference by mistake. All of the figures representing the two species (*Nisusia rara* and *Eoorthis thyone*) happened to be grouped on the same preliminary plate and when two figures were chosen to represent *Nisusia rara* in the paper referred to, one of the figures representing *Eoorthis thyone* was accidentally included.)

Eoorthis thyone WALCOTT, 1908, idem, pp. 105-106, Pl. X, figs. 7 and 7a. (Described and discussed as below as a new species. Figs. 7 and 7a are copied in this monograph as figs. 70B and 70C, respectively.)

FIGURE 70.—*Eoorthis thyone* Walcott. A, Natural cast of a ventral valve, the type specimen, showing cast of a pseudospondylium (U. S. Nat. Mus. Cat. No. 52378). B, Natural cast of a dorsal valve (U. S. Nat. Mus. Cat. No. 52377a). C, Cast of interior of dorsal valve (U. S. Nat. Mus. Cat. No. 52377b).

The specimens represented are from Middle Cambrian Marjum limestone, 2.5 miles (4 km.) east of Antelope Springs, in the ridge east of Wheeler Amphitheater, House Range, Millard County, Utah (fig. 70A from Locality 3x, and figs. 70B and 70C from Locality 11q). Figure 70A was published [Walcott, 1908d, Pl. IX, fig. 13] as representing the ventral valve of *Nisusia rara* and was given Cat. No. 52295a. As explained in the note under the first reference in the synonymy this was a mistake. Figures 70B and 70C are copied from Walcott [1908d, Pl. X, figs. 7 and 7a, respectively].

In outline and size this species resembles *Eoorthis wichitaensis* (Walcott) (Pl. XCIV, figs. 1, 1a-n), but in its sharp, uniform, radiating ribs it differs from that and other species having a somewhat similar outline. The ribs radiate from the beak and increase in number by interpolation of new ribs at irregular distances from the beak. Nothing is known of the area of either valve. A cast of the interior of a dorsal valve shows rather large muscle scars.

A large ventral valve has a length of 8 mm.; width, 9 mm.; substance of shell unknown.

Observations.—This species was at first compared with *Nisusia (Jamesella) nautes* (Walcott) (Pl. XCIII, figs. 6, 6a–b), but the surface ribs are more regular and less numerous. It also occurs 1,800 feet higher in the stratigraphic section than *N. (J.) nautes*.

FORMATION AND LOCALITY.—**Middle Cambrian:** (3x) About 2,200 feet (670.6 m.) above the Lower Cambrian and 2,200 feet (670.6 m.) below the Upper Cambrian, in the limestones forming 1d of the Marjum limestone [Walcott, 1908f, p. 180]; and (11q) about 2,350 feet (716.3 m.) above the Lower Cambrian, and 2,050 feet (624.8 m.) below the Upper Cambrian, in the limestones forming 1c of the Marjum limestone [Walcott, 1908f, p. 180]; both 2.5 miles (4 km.) east of Antelope Springs, in ridge east of Wheeler Amphitheater [Walcott, 1908f, Pls. XIII and XV], House Range, Millard County, Utah.

EOORTHIS TULLBERGI (Walcott).

Plate XCV, figure 3.

Orthis (Plectorthis) tullbergi WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 271. (Characterized as a new species.)
Orthis (Plectorthis) tullbergi WALCOTT, MOBERG and SEGERBERG, 1906, Medd. från Lunds Geol. Fältklubb, Ser. B, No. 2 (Aftryck ur K. Fysiografiska Sällskapet's Handl., N. F., Bd. 17), p. 69, Pl. II, fig. 3. (Characterized in Swedish. Fig. 3, in common with the remaining figures on Pl. II of Moberg and Segerberg's paper, was copied from a preliminary photograph of Pl. XCV of this monograph.)

The transverse outline and simple strong ribs of *Eoorthis tullbergi* serve to distinguish it from *E. christianix* (Kjerulf) and *E. daunus* (Walcott).

Moberg and Segerberg [1906, pp. 69–70] are inclined to consider this form as identical with *Eoorthis christianix*. Since reading their remarks and conclusions I have studied the material representing the two forms *Eoorthis christianix* and *E. tullbergi* and have decided to leave the latter as a distinct species. There may be a complete gradation of form and surface characters between the two shells, but I do not find it in the numerous specimens before me.

The specific name was given in honor of Mr. S. A. Tullberg.

FORMATION AND LOCALITY.—**Passage beds** between the Upper Cambrian and the Ordovician: (390) Boundary stratum between the *Orthoceras* limestone and the *Ceratopyge* limestone [Moberg and Segerberg, 1906, p. 69], at Alunbruk (alum works), southern part of Oeland Island, Sweden.

EOORTHIS WICHITAENSIS (Walcott).

Plate XCIV, figures 1, 1a–o, 1u.

Orthis (Plectorthis) wichitaensis WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 271–272. (Characterized essentially as below as a new species.)

In general form and outline this shell is related to *Eoorthis desmopleura* (Meek) and *E. remnicha* (Winchell). Its convexity and differences in the radial ribbing and striation separate it from the former species, and it occurs in an older geological formation. Its convexity and surface characters distinguish it from *E. remnicha*. The series of figures illustrating the species will enable the student to study all that is known to me of the species.

A considerable number of relatively smooth shells that occur in the collection are designated as the variety *laeviusculus*, but it is often difficult to separate them from the more finely ribbed specimens that are typical of the species.

FORMATION AND LOCALITY.—**Lower Ordovician:** (360a) Red siliceous limestone on west side of Trout Creek, below Bergen Park, 7 miles (11.2 km.) north-northwest of Manitou, El Paso County, Colorado.

Upper Cambrian: (12j) Lower part of Arbuckle limestone at Small Hill, 2 miles (3.2 km.) southwest of Signal Mountain, about 8 miles (12.8 km.) west of Fort Sill; and (9z) basal beds of the Arbuckle limestone, about 25 feet above the heavy-bedded limestone, near the middle of the west half of sec. 13, T. 4 N., R. 13 W., about 13 miles (20.8 km.) northwest of Fort Sill; both in Comanche County, Oklahoma.

(9q) About 10 feet (3 m.) above the porphyry contact and 90 feet (27.4 m.) below the Arbuckle limestone in limestones of the Reagan sandstone, in middle of west half of sec. 2, T. 4 N., R. 13 W.; (9u) about 195 feet (59.4 m.) above the porphyry contact in the limestones of the Reagan sandstone, in SE. $\frac{1}{4}$ NE. $\frac{1}{4}$ sec. 2, T. 4 N., R. 13 W.; (9s) about 85 feet (26 m.) below the Arbuckle limestone in the limestones of the Reagan sandstone, near middle of west half of sec. 13, T. 4 N., R. 13 W.; all about 15 miles (24.2 km.) northwest of Fort Sill, Comanche County, Oklahoma.

(12k) Limestones of the Reagan sandstone (in the section 7 miles (11.2 km.) north of Springer this horizon is about 225 feet (69 m.) above the porphyry contact and 55 feet (17 m.) below the Arbuckle limestone), on the west

side of Honey Creek, near the southeast corner of sec. 35, T. 1 S., R. 1 E., Ardmore quadrangle (U. S. Geol. Survey), Carter County; (12n) limestones of the Reagan sandstone (in the section 7 miles (11.2 km.) north of Springer this horizon is about 240 feet (73 m.) above the porphyry contact and 40 feet (12 m.) below the Arbuckle limestone), NW. $\frac{1}{4}$ sec. 1, T. 2 S., R. 1 E., Ardmore quadrangle (U. S. Geol. Survey), Carter County; and (12p) *about 225 feet (69 m.) above the igneous rocks in the limestones of the Reagan sandstone, at the northwest extremity of the Arbuckle Mountains, about 4 miles (6.4 km.) east of Homer, Carter County; all in Oklahoma.*

(14b) Limestone on Cold Creek at north end of gorge opposite the north end of Sponge Mountain, 2 miles (3.2 km.) south of the San Saba County line, in Llano County; (68) limestone on Packsaddle Mountain, Llano County; and (71) limestone in Cold Creek Canyon, Burnet County; all in Texas.

(150a) Limestone on the east side of Dry Creek, above the mouth of Pass Creek; and (153a) limestone in ravine on west side of Dry Creek, near the mouth of Pass Creek; both about 5 miles (8 km.) north of Hillsdale, Threeforks quadrangle (U. S. Geol. Survey), Gallatin County, Montana.

(151) Limestone in point overlooking Churn Canyon, on the west side of the Bridger Range, Gallatin County, Montana.

(302e) Limestone near the top of the Deadwood formation, in Middle Popo Agie Canyon, near Lander, Fremont County, Wyoming.

Middle Cambrian: (369a) Limestone in or just beneath the "Edgewise beds" near Elvins, 6 miles (9.6 km.) south of Bonnetterre, St. Francois County, Missouri.

EOORTHIS WICHITAENSIS LEVIUSCULUS (Walcott).

Plate XCIV, figures 1p-s.

Orthis (Plectorthis) wichitaensis leviusculus WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 272. (Characterized essentially as below as a new variety.)

A variety with small, narrow, numerous ribs is given the above name. So many gradations exist between it and the typical forms of *E. wichitaensis* (Walcott) that the figures are arranged on the plate rather to show the gradations in surface characters than to bring out this special variety.

FORMATION AND LOCALITY.—**Upper Cambrian:** (12k) Limestones of the Reagan sandstone (in the section 7 miles (11.2 km.) north of Springer this horizon is about 225 feet (69 m.) above the porphyry contact and 55 feet (17 m.) below the Arbuckle limestone), on the west side of Honey Creek, near the southeast corner of sec. 35, T. 1 S., R. 1 E., Ardmore quadrangle (U. S. Geol. Survey), Carter County; (12n) limestones of the Reagan sandstone (in the section 7 miles (11.2 km.) north of Springer this horizon is about 240 feet (73 m.) above the porphyry contact and 40 feet (12 m.) below the Arbuckle limestone), NW. $\frac{1}{4}$ sec. 1, T. 2 S., R. 1 E., Ardmore quadrangle (U. S. Geol. Survey), Carter County; and (12p) *about 225 feet (69 m.) above the igneous rocks in the limestones of the Reagan sandstone, at the northwest extremity of the Arbuckle Mountains, about 4 miles (6.4 km.) east of Homer, Carter County; all in Oklahoma.*

(14b) Limestone at north end of gorge opposite the north end of Sponge Mountain, 2 miles (3.2 km.) south of the San Saba County line; and (68) limestone in Packsaddle Mountain; both in Llano County, Texas.

EOORTHIS WIMANI (Walcott).

Plate XCV, figures 4, 4a-d.

Orthis (Plectorthis) wimani WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 272. (Discussed essentially as below as a new species.)

Orthis (Plectorthis) wimani Walcott, MOBERG and SEGERBERG, 1906, Medd. från Lunds geol. Fältklubb, Ser. B, No. 2 (Afttryck ur K. Fysiografiska Sällskapets Handl., N. F., Bd. 17), p. 70, Pl. II, figs. 4, 4a-d; Pl. III, figs. 14, 15a-b. (Discussed in Swedish. Figs. 4, 4a-d, in common with the remaining figures on Pl. II of Moberg and Segerberg's paper, were copied from a preliminary photograph of Pl. XCV of this monograph.)

This shell is distinguished from *Eoorthis christianix* (Kjerulf) and *E. daunus* (Walcott) by the rounded, narrow, simple ribs and the less transverse and more rounded outline. A ventral valve discovered after the drawings were made shows a well-defined pseudospondylium, with the tripartite division as seen in *E. remnicha* (Winchell) (Pl. XCI, fig. 1e). Two strong main vascular sinuses extend forward from the lateral divisions of the umbonal cavity nearly to the front of the valve, corresponding in position to those of the dorsal valve (Pl. XCV, fig. 4a). The cast of the dorsal valve indicates the presence of rather strong crura, crural plates, dental sockets, and delthyrium.

The ventral valve is rather strongly convex, and the dorsal valve about half as much so. The average size is 6 to 7 mm. in diameter, the ventral valve being about 1.5 mm. larger

than the dorsal. The largest ventral valve in the material available for study has a length of 9 mm.

The specific name was given in honor of Dr. Carl Wiman.

FORMATION AND LOCALITY.—Passage beds between the Upper Cambrian and the Ordovician: (310j) *Ceratopyge* limestone at Borgholm, Oeland Island, Sweden.

(8x) Limestone at Slemmestad, about 3 miles (4.8 km.) southwest of Christiania, Norway.

Upper Cambrian: (390b [Moberg and Segerberg, 1906, p. 71]) Limestones of the *Shumardia* zone (zone 3) at Fogel-sång, 5 miles (8 km.) east of Lund, Province of Malmöhus; and (390c [Moberg and Segerberg, 1906, p. 70]) *Ceratopyge* slate (Zone 3) at Wentlinge, on Oeland Island; both in Sweden.

(323w) Black argillaceous shale of Division 3a3, at Christiania, Norway.

EOORTHIS ZENO Walcott.

Text figures 71A–B'.

Eoorthis zeno WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 3, p. 106, Pl. 10, fig. 8. (Discussed as below as a new species. Fig. 8 is copied in this monograph as fig. 71A.)

In outline the ventral valve of this species is somewhat similar to that of some forms of *Eoorthis remnicha winfieldensis* (Walcott) (Pl. XCI, fig. 2d), but it differs in having finer radiating ribs and in its smaller size.

It is also much smaller than *Eoorthis newberryi* Walcott, and it occurs 4,390 feet (1,338 m.) lower in the same stratigraphic section. The character of the surface is shown by text figure 71B', and the general form by text figure 71A. I do not know of any similar form, with such regular, fine, sharp radiating ribs, from the

FIGURE 71.—*Eoorthis zeno* Walcott. A, A', Exfoliated ventral valve (U. S. Nat. Mus. Cat. No. 52397a). B, Fragment of dorsal valve (U. S. Nat. Mus. Cat. No. 52397b). B', Enlargement of portion of surface of B (X 10).

The specimens represented are from Locality 540, Middle Cambrian Ute limestone in Blacksmith Fork, about 10 miles (16.1 km.) east of Hyrum, Cache County, Utah. Figure 71A is copied from Walcott [1908d, Pl. X, fig. 8]. It is the type specimen.

Cambrian. The largest ventral valve in the collection has a length of 10 mm.; width, 18 mm.

FORMATION AND LOCALITY.—Middle Cambrian: (31e and 540)^a About 900 feet (274.3 m.) above the Brigham quartzite and 3,300 feet (1,005.8 m.) below the Upper Cambrian in the limestone forming 1b of the Ute limestone [Walcott, 1908f, p. 196], in Blacksmith Fork Canyon, about 10 miles (16.1 km.) east of Hyrum, Cache County, Utah.

EOORTHIS sp. undt. a (Pompeckj).

Orthis sp., POMPECKJ, 1896, Jahrb. K.-k. geol. Reichsanstalt für 1895, Bd. 45, Hft. 3, p. 514, Pl. XV, fig. 6. (Characterized in German; see below for translation.)

Orthis (Plectorthis) sp. (Pompeckj), WALCOTT (in part), 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 272–273. (Original description copied.)

This species appears, from the illustration given by Pompeckj [1896b, Pl. XV, fig. 6], to belong to the genus *Eoorthis*. The material is too imperfect for specific determination. The original description is as follows:

Some impressions of dorsal valves depart from *Orthis romingeri*. The ribs are remarkably broad, flat, and separated by narrow interspaces; ribs may be observed to be split several times.

FORMATION AND LOCALITY.—Middle Cambrian: (345 [Pompeckj, 1896b, p. 514]) Greenish shale in the *Paradoxides* zone, on the Dlouhá Hora, above the brook of Sbirov, near Skrej, Bohemia, Austria-Hungary.

EOORTHIS sp. undt. b (Pompeckj).

Orthis sp. POMPECKJ, 1896, Jahrb. K.-k. geol. Reichsanstalt für 1895, Bd. 45, Hft. 3, p. 514, Pl. XV, fig. 7. (Characterized in German; see p. 793 for translation.)

Orthis (Plectorthis) sp. (Pompeckj), WALCOTT (in part), 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 272–273. (Original description copied.)

^a 540 is the type locality.

Pompeckj [1896b, p. 514] mentions another species of *Orthis* that appears to belong to the genus *Eoorthis*. The material, which is too imperfect for specific determination, was described as follows:

The impression of a dorsal valve departs from *Orthis romingeri* in its greater breadth and less distinct ribbing.

FORMATION AND LOCALITY.—Middle Cambrian: (345e [Pompeckj, 1896b, p. 514]) Greenish shale in the *Paradoxides* zone in the gorge above Luh, near Skrej, Bohemia, Austria-Hungary.

EOORTHIS sp. undt. c (Walcott).

Plate LXXXIX, figure 7.

Orthis (Plectorthis) sp. undt. WALCOTT, 1906, Proc. U. S. Nat. Mus., vol. 30, p. 571. (These various shells are described and discussed essentially as below as sp. undt. c, d, and e.)

This species is represented by a single specimen of the ventral valve. Ventral valve convex, with the apex curving gently downward from the highest point to the cardinal area, transverse; length, 2.5 mm.; width, 3 mm.; hinge line a little shorter than the greatest width; cardinal area sloping slightly forward from the hinge line.

Surface marked by about 16 strong, nearly regular, rounded, radiating ribs, that are crossed by fine, concentric striæ, lines of growth, and one strong ridge indicating interruption of growth.

Observations.—This little shell was at first placed with *Eoorthis agreste* (Walcott) (Pl. LXXXIX, fig. 6), but further study showed that its greatest convexity, elevated apex, and stronger ribs distinguished it from that species.

FORMATION AND LOCALITY.—Middle Cambrian: (C26) Near the top of the black oolite group in the uppermost layers of the Changhia formation [Blackwelder, 1907a, p. 33 (part of the last list of fossils)]; 2 miles (3.2 km.) north-northeast of Changhia, Shantung, China.

EOORTHIS sp. undt. d (Walcott).^a

Plate LXXXIX, figure 8.

A larger shell of the type of sp. undt. c occurs in Shensi, in the central portion of the Kichou formation. It has a length of 6.5 mm. and a width of 7.5 mm. The surface is marked by numerous radiating ribs, similar to those of the shell from Changhia, also concentric striæ and several ridges resulting from interruption of growth.

FORMATION AND LOCALITY.—Middle Cambrian: (C71) Massive cliff-making limestones in the central portion of the Kichou formation [Willis and Blackwelder, 1907, pp. 139 and 145 (2d list of fossils)], 4 miles (6.4 km.) south-southwest of Tungyu, Shansi, China.

EOORTHIS sp. undt. e (Walcott).^a

A third shell that appears to be a dorsal valve was found associated with Middle Cambrian trilobite fragments in limestone pebbles in river gravel. The surface is partly exfoliated, but it shows rounded, radiating ribs and concentric ridges, similar to those on the two specimens described above as sp. undt. c and sp. undt. d.

FORMATION AND LOCALITY.—Upper Cambrian: (C67) Stream gravels used in making the railroad grade, 0.33 mile (0.5 km.) west of the west city gate, Tsinan, Shantung, China.

Genus *FINKELNBURGIA* Walcott.

Orthis (Finkelburgia) WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 277-278. (Characterized and discussed as below as a new subgenus.)

Finkelburgia WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 4, Pl. XI, and pp. 142 and 148. (Classification of genus.)

This genus is based upon two species that differ from *Eoorthis* in having thick shells and strongly marked vascular trunks in the ventral valve. The type of the genus, *Finkelburgia finkelburgi*, with its acuminate and sometimes alate cardinal extremities and subequally convex

^a See synonymy for *Eoorthis* sp. undt. c.

valve, is a very strongly marked type; the second species, *F. osceola*, has obtuse cardinal extremities, and most of the examples closely resemble in form *Eoorthis remnicha* (Winchell). It is only when the specimens from the fine-grained sandstone of Trempealeau are studied that one finds the thick shell and strong interior markings that are unknown in species of the genus *Eoorthis*.

This genus is named after Mr. W. A. Finkelnburg, of Winona, Minnesota, who has been one of the most intelligent and enthusiastic collectors of Cambrian and Ordovician fossils in Minnesota in recent years.

Type.—*Orthis (Finkelnburgia) finkelnburgi* Walcott.

FINKELNBURGIA FINKELNBURGI (Walcott)

Plate XCIII, figures 2, 2a-e.

Orthis (Finkelnburgia) finkelnburgi WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 278-279. (Described and discussed as below as a new species.)

Shell transverse with the cardinal extremities acuminate and in some examples almost alate. On the ventral valve the hinge line slopes toward the beak at a low angle; in the dorsal valve it is nearly straight. There is considerable variation in the height and width of the shell, this feature depending upon the extension of the cardinal angles. The convexity of the valves is subequal. In some examples the ventral valve is much more elevated and convex than in others, and the same is true of the dorsal valve. A low, clearly defined mesial sinus occurs on the dorsal valve, being strongest in young shells, and there is frequently a flattening of the mesial area on the ventral valve.

The surface is marked by fine, rounded, radiating costæ, crossed by concentric lines, and, occasionally, ridges of growth. In a ventral valve 7 mm. in length, 11 mm. in width, there are two costæ in a distance of 1 millimeter.

The largest specimen of a ventral valve in the collection has a length of 10 mm. with a width of 18 mm. The average shell is less than 8 mm. in length.

The cardinal area of the ventral valve is relatively high. It extends backward over the hinge line at an angle varying from 15° to 45° from the plane of the valve. The delthyrium is of moderate width and apparently partly covered by a deltidium. The cardinal area of the dorsal valve averages about one-half the height of that of the ventral valve, although in some shells it is fully two-thirds as high. It extends backward at an angle of about 70° to the plane of the valve. It is divided midway by a strong delthyrium. None of the specimens in the collections show whether there was a chilidium present or not.

In the interior of the ventral valve the strong teeth were supported by dental plates that extend to the bottom of the valve and bound the umbonal cavity (pseudospondylium). The only traces of the vascular system are the bases of strong vascular trunks, as shown in Plate XCIII, figure 2. The positions of the diductor and adductor muscle scars are shown in figure 2. The latter appear to have been carried into a very narrow space on an elevated ridge between the deep impressions made by the main vascular trunks; in figure 2a the points of attachment of the muscles are well advanced into the valve.

In the interior of the dorsal valve a cast of the interior of the pseudocruralium appears to have a small cardinal process, or callosity, but its presence is too doubtful to state that the cardinal process is present; there are traces of a median septum shown on the central ridge toward the center of the valve. The cardinal process occurs in the anterior half of the umbonal cavity. The casts of the interior show that the crura are short and well defined, with relatively strong dental sockets beside them. The only traces of the muscle scars observed are those of the adductor, as shown in figure 2c.

Observations.—The exterior surface and size of this shell recalls *Finkelnburgia osceola* (Walcott). It differs, however, in the acuminate ventral angles and strongly convex dorsal valve. In form the elongate cardinal angles relate this species to *Otusia sandbergi* (Winchell), but in surface and interior markings it materially differs from the latter.

The specific name was given in honor of Mr. W. A. Finkelnburg.

FORMATION AND LOCALITY.—Upper Cambrian: (78 and 78s) "St. Croix sandstone," quarry near St. Croix River in suburbs of Osceola, Polk County; (81) "St. Croix sandstone" 1 mile (1.6 km.) east-northeast of Devils Lake, Sauk County; (81b) "St. Croix sandstone" near Devils Lake, Sauk County; and (83, 83', 135b, and 135c)^a "St. Croix sandstone" near Trempealeau, Trempealeau County; all in Wisconsin.

(339f) "St. Croix sandstone" near Minneiska (Miniska) on Mississippi River near the line between Wabasha and Winona counties, Minnesota.

FINKELNBURGIA OSCEOLA (Walcott).

Plate XCIII, figures 1, 1a-h.

Orthis (*Finkelnburgia*) *osceola* WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 279. (Discussed essentially as below as a new species.)

The general form of this species is similar to that of *Eoorthis remnicha* (Winchell) except that it is usually more transverse. It is a smaller shell, averaging for the ventral valve a length of 8 mm. and width of 11 mm., while *E. remnicha* averages 12 mm. in length and 14 to 16 mm. in width in the adult shell. The radiating costæ are more uniformly rounded and regular, and more numerous, except when compared with the variety *texana*. The shell of *Finkelnburgia osceola* is thick, like other forms of the genus, with a result that the vascular markings are definitely outlined. In figure 1d the vascular markings are beautifully shown; also, the large main vascular sinuses so characteristic of many species of *Billingsella*. The cardinal process and median septum are well brought out in the cast, figure 1f. Some of the dorsal valves approach quite closely to those of *E. remnicha sulcata* (Walcott).

The specific name is derived from Osceola, Wisconsin.

FORMATION AND LOCALITY.—Upper Cambrian: "St. Croix sandstone" at the following localities: (78 and 78s) Quarry near St. Croix River, in suburbs of Osceola, Polk County; (78b) 50 feet (15 m.) above St. Croix River, near the landing at Osceola, Polk County; (79a) quarry and ledge 0.5 mile (0.8 km.) southeast of the county courthouse, Menomonie, Dunn County; (80) 0.33 mile (1.1 km.) southwest of the railway depot, Menomonie, Dunn County; (79b) near Hudson, St. Croix County; (80a) 4 miles (6.4 km.) north of Reedsburg, Sauk County; (83, 83' and 135c)^b near Trempealeau, Trempealeau County; (85x) near Mazomanie, Dane County; and (328i) 0.33 mile (1.1 km.) west of the railway station, Lodi, Columbia County; all in Wisconsin.

(339g) Just below the *Dicellosephalus minnesotensis* zone, near Winona, Winona County, Minnesota.

(341) Sandstone near Lansing, Allamakee County, Iowa.

FINKELNBURGIA OSCEOLA CORRUGATA (Walcott).

Orthis (*Finkelnburgia*) *osceola corrugata* WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 280. (Characterized as below as a new variety.)

At two of the localities at which *Finkelnburgia osceola* (Walcott) occurs there are also found a few specimens with strong concentric ridges formed by the piling up of lines of growth. The shell has a corrugated appearance that is very distinctive, and it is designated a variety.

FORMATION AND LOCALITY.—Upper Cambrian: (78 and 78s)^b "St. Croix sandstone," quarry near St. Croix River, in the suburbs of Osceola, Polk County, Wisconsin.

(339g) Just below the *Dicellosephalus minnesotensis* zone, near Winona, Winona County, Minnesota.

Superfamily STROPHOMENACEA Schuchert.

Family STROPHOMENIDÆ King.

Subfamily RAFINESQUINÆ Schuchert.

Genus EOSTROPHOMENA Walcott.

[*ἑως*, dawn; and *Strophomena* (*στροφῆ*, a twist; and *μήνη*, the moon, a crescent).]

Strophomena (*Eostrophomena*) WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 256. (Characterized as below as a new subgenus.)

Eostrophomena WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 4, Pl. XI, and pp. 142 and 148. (Classification of genus.)

^a 83 is the type locality.

^b 83' is the type locality.

The description of the type species gives all that is known of the genus. It differs from *Strophomena* in having the cardinal process in the dorsal valve merged into a ridge formed by the extension of the crural plates along the posterior margin so as to cover the delthyrium and unite at the median line.

Type.—*Strophomena (Eostrophomena) elegantula* Walcott.

Observations.—The cardinal process is more like that of *Orthothetes* than that of *Strophomena*; it differs from both in being more simple in its construction. It is probable that there is a group of shells having the characters of *Eostrophomena elegantula* (Walcott), but owing to the difficulty of obtaining interiors of the valves, it is impossible to designate them. *Strophomena aurora* Billings [1865a, p. 218] is one of these; also, *Leptaena decipiens* [Billings, 1862c, p. 74].

EOSTROPHOMENA ELEGANTULA (Walcott).

Plate XCV, figures 6, 6a-b.

Strophomena (Eostrophomena) elegantula WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 256-257. (Described and discussed as below as a new species.)

Strophomena (Eostrophomena) walcotti MOBERG and SEGERBERG, 1906, Medd. från Lunds Geol. Fältklubb, Ser. B, No. 2 (Aftryck ur K. Fysiografiska Sällskapets Handl., N. F., Bd. 17), p. 71, Pl. II, figs. 6, 6a-b; Pl. III, fig. 16?. (Described and discussed in Swedish. The specific name "*walcotti*" is proposed because of the preoccupation of "*elegantula*." The generic value now assigned to *Eostrophomena* permits the use of "*elegantula*." Figs. 6, 6a-b, in common with the remaining figures on Pl. II of Moberg and Segerberg's paper, were copied from a preliminary photograph of Pl. XCV of this monograph.)

General form transversely subsemicircular or subelliptical, greatest width at the straight hinge line. Surface concavo-convex and marked by fine, radiating, even striae, separated into flat bands by stronger and more prominent striae or ribs; fine concentric striae, and more or less prominent lines of growth cross the radiating striae. The ventral valve is slightly convex, with low umbo and small, incurved apex. The dorsal valve is flattened in the umbonal region and concave toward the margins; the interior shows a narrow, rounded median furrow, also rounded crural plates that unite with the cardinal process to form a continuous ridge covering the anterior portion of the delthyrium; the dental sockets appear to have been relatively large and deep; the adductor muscle scars are a little to the front, as shown in figure 6b.

A ventral valve 6 mm. wide has a length of 4 mm., and a dorsal valve 5.5 mm. wide is 3 mm. in length.

Observations.—The concavo-convex shells and the ridge representing the cardinal process place this little shell with the strophomenoid forms, but as no described genus possesses the characters shown a genus is made to receive it.

FORMATION AND LOCALITY.—**Passage beds** between the Upper Cambrian and the Ordovician: (310j) *Ceratopyge limestone, at Borgholm*: (310 [Moberg and Segerberg, 1906, description of Pl. III]) *Ceratopyge limestone (Zone 4)* at Ottenby; and (390e [Moberg and Segerberg, 1906, pp. 71 and 109]) "*Apatoccephalus zone of the Ceratopyge suite*," at Ottenby; all on Oeland Island, Sweden.

Superfamily PENTAMERACEA Schuchert.

Family SYNTROPHIIDÆ Schuchert.

Genus SWANTONIA Walcott.^a

Swantonia WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 296. (Mentioned as below as a new genus.)

Swantonia WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 4, Pl. XI, and pp. 142 and 148. (Classification of genus.)

The description of the type species includes that of the genus, as there is only one other species now referred to the genus, and that is very imperfectly known.

^a Prior to the definition of the genus *Swantonia* the species now placed under that genus were referred to the following genera:

Camarrella Billings [1861b, p. 10; 1861c, p. 949; 1862e, p. 221; 1863, p. 284].
Camarrella Walcott [1886b, p. 122; 1891a, p. 613].

Camarrella? Hall and Clarke [1893, p. 220].
Protorhyncha? Schuchert [1897, p. 334].

Type.—*Camerella antiqua* Billings [1861b, p. 10].

The generic name is derived from the town of Swanton, Vermont, near which the type species occurs.

SWANTONIA ANTIQUATA (Billings).

Plate CIV, figures 5, 5a-b.

- Camerella antiquata* BILLINGS, 1861, Geol. Survey Canada, Paleozoic Fossils, vol. 1, pp. 10-11, fig. 13, p. 10. (Described and discussed as a new species.)
- Camerella antiquata* BILLINGS, 1861, Report on the Geology of Vermont, vol. 2, p. 949, fig. 353. (Copy of preceding reference.)
- Camerella antiquata* BILLINGS, 1862, Report on the Economic Geology of Vermont, by Hager, p. 221, fig. 353. (Copy of Billings, 1861b, pp. 10-11, and fig. 13.)
- Camerella antiquata* BILLINGS, 1863, Geol. Survey Canada, Fifteenth Rept. Progress, fig. 290, p. 284. (No text reference. Fig. 290 is copied from Billings, 1861b, fig. 13, p. 10.)
- Camarella antiquata* Billings, WALCOTT, 1886, Bull. U. S. Geol. Survey No. 30, pp. 122-123, Pl. VII, fig. 8. (Original description, Billings, 1861b, pp. 10-11, copied. The specimen represented by fig. 8 is redrawn in this monograph, Pl. CIV, fig. 5.)
- Camarella antiquata* Billings, WALCOTT, 1891, Tenth Ann. Rept. U. S. Geol. Survey, p. 613, Pl. LXXII, fig. 3. (No text reference. Fig. 3 is copied from fig. 8 of the preceding reference.)
- Camarella ? antiquata* Billings, HALL and CLARKE, 1893, Nat. Hist. New York, Paleontology, vol. 8, pt. 2, pp. 220-221. (Mentioned in discussion of genus *Camarella*.)
- Protorhyncha ? antiquata* (Billings), SCHUCHERT, 1897, Bull. U. S. Geol. Survey No. 87, p. 334. (Merely changes generic reference.)
- Swantonina antiquata* (Billings), WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 296-297. (Described and discussed as below.)

Ventral valve ovate, moderately convex; apex pointed and incurved over the area nearly to the plane of the margins of the valve; surface marked by from 8 to 12 or more rounded ribs that extend back well toward the apex; a slight flattening of the median portion suggests that a shallow median sinus may be found on old shells. The shell illustrated has a length and width of 11 mm.

A cast of the interior of a ventral valve shows no traces of muscle scars or vascular markings; two strong teeth are indicated, also a narrow, strong, concave shelf or area; the area or shelf is free from contact with the bottom of the valve, a recess or chamber existing beneath it.

Observations.—The area or shelf may be considered as a short, free spondylium, corresponding to the short spondylium of *Camarella volborthi* Billings as illustrated by Hall and Clarke [1892c, Pl. LXII, fig. 18]. *Swantonina* is closely related to *Camarella*, but it differs in the absence of a supporting median septum beneath the spondylium of the ventral valve. No specimens of the dorsal valve have been observed.

FORMATION AND LOCALITY.—Lower Cambrian: (319e)^a Sandy shales 2 miles (3.2 km.) east of Swanton, Franklin County, Vermont.

SWANTONIA WEEKSI Walcott.

Plate CIV, figure 6.

Swantonina weeksi WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 297. (Characterized as below as a new species.)

This shell has the general form of *Swantonina antiquata* (Billings), but the ribs are finer, more numerous, and crossed by fine, sharp, concentric striae. Only the exterior of the ventral valve appears to be represented in the collection made by Mr. F. B. Weeks.

FORMATION AND LOCALITY.—Lower Cambrian: (1v) Shales of No. 3 of the Silver Peak group, Barrel Spring section [Walcott, 1908f, p. 189], 3 miles (4.8 km.) north of Valcalda Spring and 4 miles (6.4 km.) west-northwest of the Drinkwater mine, Silver Peak quadrangle (U. S. Geol. Survey), Esmeralda County, Nevada.

^a Billings [1861b, p. 11] gives the locality as 1.5 miles (2.4 km.) east of Swanton, Vermont.

Genus *SYNTROPHIA* Hall and Clarke.^a

- Syntrophia* HALL and CLARKE, 1892, Nat. Hist. New York, Paleontology, vol. 8, pt. 1, footnote, p. 270. (Discusses species which appear to belong to a distinct genus and announces the future use of the term *Syntrophia* to include them.)
- Syntrophia* HALL and CLARKE, 1893, idem, pt. 2, pp. 216-218. (Described and discussed as a new genus, copying the original note proposing the genus. The description of "*Triplesia lateralis*" Whitfield, which is given on p. 217, is copied in this monograph; see below.)
- Syntrophia* HALL and CLARKE, HALL, 1894, Thirteenth Ann. Rept. State Geologist New York for 1893, vol. 2, pp. 836-837. (Copies the description of "*Triplesia lateralis*" given on p. 217 of the preceding reference.)
- Syntrophia* HALL and CLARKE, WALCOTT (in part), 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 288-289. (Gives an essential copy of the description of "*Triplesia lateralis*" given by Hall and Clarke, 1893b, p. 217, a description which is copied below, and discusses the genus essentially as below. Species were included in the genus which are now placed under *Huenella*.)
- Syntrophia* HALL and CLARKE, GRABAU and SHIMER, 1907, North American Index Fossils, vol. 1, p. 270. (Described.)
- Syntrophia* HALL and CLARKE, WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 4, Pl. XI, and pp. 142 and 148. (Classification of genus.)

The description of "*Triplesia lateralis*" by Hall and Clarke [1893b, p. 217] follows:

Shell transversely elongate, biconvex with a straight hinge line whose length nearly equals the greatest diameter of the valves, and each valve is medially divided by an open delthyrium. The external surface is smooth, with fine concentric lines visible only about the margins; the inner shell layers show a strongly fibrous radiating structure without punctation. The pedicle valve bears a more or less clearly developed median sinus and the brachial valve a broad, indistinct fold.

On the interior the teeth are very small, lying at the extremities of the delthyrial margins and supported by dental plates which converge and unite before reaching the bottom of the valve. Thus is formed a deep but short spondylium, which is supported, near its apical portion, by a median septum, but is free for fully one-half its length.

In the brachial valve there are also two convergent plates bounding the deltidial cavity, larger and stronger than those of the opposite valve. These plates may rest upon the bottom of the valve, and probably always do so toward the posterior extremity, but anteriorly they become free, forming a spondylium which is supported by a median septum extending beyond the anterior edge of the plate. Thus these two valves which are very similar in exterior, the pedicle valve being only slightly the more convex and with a low median sinus, are also closely alike on the interior, each being furnished with a spondylium.

Type.—*Triplesia lateralis* Whitfield.

Observations.—Hall and Clarke [1893b, p. 216] referred *Orthis barabuensis* and *Triplesia primordialis* among Cambrian species to *Syntrophia*, and of Ordovician species, *Triplesia lateralis*, *Stricklandinia? arethusa*, *S.? arachne*, and *Camarella calcifera*.

Orthis? armada Billings, of the Lower Ordovician, certainly has a close resemblance in the spondylium of its ventral valve to this genus, and it may represent a radially striated form, as suggested by Hall and Clarke [1893b, p. 218]. Concerning the relations of *Syntrophia* to *Stricklandinia*, they consider that the structures represented in the species referred to the former genus may be the equivalents of those represented by the *Stricklandinias* of the later Silurian and Devonian. Billings [1862b, p. 84] noted the relationship existing between his *Camarella calcifera* and *Stricklandinia*. It is probable that *S.? arachne*, *S. arethusa*, and similar forms should be referred to a distinct genus. They are not typical *Stricklandinias* and they differ in surface and shape from *Syntrophia lateralis*.

The Cambrian type of *Syntrophia* is *S. rotundata* of the Upper Cambrian. It has a spondylium in each valve supported by a median septum, and a short area divided by a large open delthyrium.

The structure of the shell of *Syntrophia* is fibrous, with rows of minute pores between the fibers.

^a The synonymy for this genus does not give a complete record of the various genera under which the species now included in *Syntrophia* were formerly placed; it gives only those references in which the genus is discussed or described. To complete the record for the species taken up in this monograph the following mere generic references are listed:

Camarella Billings [1861a, p. 318; 1863, p. 231].

Orthis A. Winchell [1864, p. 228].

Camarella Billings [1865a, p. 220].

Triplesia Whitfield [1878, p. 51].

Leptæna Whitfield [1878, p. 60; 1882, pp. 171 and 195].

Triplesia Whitfield [1882, p. 172].

Triplesia Walcott [1884b, p. 75].

Triplesia Whitfield [1886, p. 303].

Triplesia Hall and Clarke [1892c, p. 270].

All of the species of the Syntrophiidæ with nonplicated, smooth surface and spondylium raised on a median septum are referred to *Syntrophia*, and the species with a more or less plicate surface, with sessile spondylium or pseudospondylium, to the genus *Huenella*. The nonplicate or smooth species are: *S. cambria* and *S. ? unxia* of the Middle Cambrian; *S. alata*, *S. barabuensis*, *S. campbelli*, *S. orthia*, *S. primordialis*, and *S. rotundata* of the Upper Cambrian; and *S. calcifera*, *S. lateralis*, and *S. nudina* of the Ordovician.

SYNTROPHIA ALATA Walcott.

Plate CIII, figures 3, 3a-e.

Syntrophia alata WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 290. (Characterized as below as a new species.)

This species is characterized by its transverse form and extended cardinal angles. Exterior surface marked by concentric striæ and lines of growth and interior surface by fine, radiating striæ. A transverse section of the ventral valve at the umbo shows the spondylium with a strong median septum supporting it. The interior of the ventral valve was marked by two strong main vascular sinuses starting from the sides of the spondylium.

FORMATION AND LOCALITY.—Upper Cambrian: (69) Limestone near Honey Creek, Burnet County, Texas.

SYNTROPHIA BARABUENSIS (A. Winchell).

Plate CII, figures 1, 1a-g.

Leptæna barabuensis (Winchell), WHITFIELD, 1882, Geology of Wisconsin, vol. 4, pt. 3, pp. 171-172, Pl. I, figs. 6 and 7. (Described and discussed; see below for copy.)

Leptæna barabuensis Winchell, WHITFIELD, 1882, idem, p. 195, Pl. III, fig. 6. (Described from a higher horizon than that containing the specimens referred to in the preceding.)

Syntrophia barabuensis (Winchell), HALL and CLARKE, 1893, Nat. Hist. New York, Paleontology, vol. 8, pt. 2, p. 216. (Changes generic reference.)

Syntrophia barabuensis (Winchell), WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 27, pp. 290-291. (Description by Whitfield copied, and species discussed as below.)

The description by Whitfield [1882, pp. 171-172] follows:

Shell of medium size or smaller, measuring about half an inch or less than half an inch along the hinge line; form semielliptical, longest on the hinge and more than half as wide again as long; extremities of the hinge often submucronate; front of the valves rounded or slightly emarginate in the middle. Ventral valve the most convex, and marked by a strong, angular mesial elevation, nearly one-fourth as wide on the front of the valve as the width of the shell; area moderately high and nearly in the plane of the valve; cardinal borders very gradually sloping from the center to the extremities of the cardinal line. Dorsal valve less convex than the opposite, and marked by a subangular mesial depression, corresponding to the fold of the opposite valve; area linear. Surface of the shell apparently smooth, or at least so far as can be determined from either the internal casts or from the matrix.

I had some doubt regarding the positive identity of this species with that described by Professor Winchell [1864, p. 228] in consequence of the following remarks which occur in his description: "Surface with sixteen or eighteen ribs visible on the casts, the strongest of which limit the mesial sinus," and again, "apparently of the type of *Orthis biforta*." In examining a number of specimens, I had not been able to detect any striæ or ribs, and felt somewhat inclined to regard it as a distinct species from that one. I have, however, through the kindness of Prof. W. [Winchell], been able to make a direct comparison with one of his original specimens, and should consider them as identical. The specimen sent me has the mesial fold (of the ventral valve) remarkably strongly defined by a depressed line on each margin, the center appearing tumid, which I think is in part due to accident. The specimen corresponds closely with the ventral valve we have figured, except in the strongly defined mesial fold.

Observations.—This is the same type of *Syntrophia* as *S. primordialis*. It differs in its more rounded outlines, shallow, rounded sinus in the ventral valve, and, usually, a less pronounced fold on the dorsal valve. Evidence of a short median septum at the end of a very short spondylium in the dorsal valve is shown by one cast (Pl. CII, fig. 1g).

The species derives its specific name from its occurrence at Devils Lake, which is near Baraboo, Sauk County, Wisconsin.

FORMATION AND LOCALITY.—Upper Cambrian: "St. Croix sandstone" at the following localities: (328 [Whitfield, 1882, p. 172]) Upper layers near the north end of Devils Lake, Sauk County; (81b) near Devils Lake, Sauk County; (81o)

on the railroad track below the Cliff House, Devils Lake, Sauk County; (83) near Trempealeau, Trempealeau County; (78) quarry near St. Croix River in the suburbs of Osceola, Polk County; and (134a) in a quarry 1 mile (1.6 km.) south-east of the county courthouse in Menomonie, Dunn County; all in Wisconsin.

SYNTROPHIA CALCIFERA (Billings)

Plate CIV, figures 1, 1a-i.

Camerella calcifera BILLINGS, 1861, Canadian Naturalist, vol. 6, pp. 318-320, figs. 3a-c, p. 319. (Described and discussed as a new species. Figs. 3a-c are copied in this monograph, Pl. CIV, figs. 1, 1a, and 1b, respectively.)

Camarella calcifera BILLINGS, 1863, Geol. Survey Canada, Fifteenth Rept. Progress, figs. 247a-c, p. 231. (No text reference. Figs. 247a-c are copied from figs. 3a-c of the preceding reference.)

Camerella calcifera BILLINGS, 1865, Geol. Survey Canada, Paleozoic Fossils, vol. 1, p. 220. (Localities mentioned.)

Triplecia? calcifera (Billings), HALL and CLARKE, 1892, Nat. Hist., New York, Paleontology, vol. 8, pt. 1, p. 270. (Merely changes generic reference.)

Syntrophia? calcifera (Billings), HALL and CLARKE, 1893, idem, pt. 2, p. 218, Pl. LXII, fig. 24. (Changes generic reference.)

Syntrophia calcifera differs from *S. nundina* in its more pointed and incurved apex, stronger ventral sinus, and dorsal fold. It is more convex and rotund than *S. primordialis*.

The only interior parts known are in the form of a cast illustrated by Billings [1861a, fig. 3c, p. 319] and copied in Plate CIV, figure 1b; this indicates a well-developed spondylium and a median supporting septum in the ventral valve.

The form owes its specific name to its occurrence in the "calciferous sandrock."

FORMATION AND LOCALITY.—Lower Ordovician: (319t)^a "Calciferous sandrock" at St. Timothy on the St. Lawrence, near the head of the Beauharnois Canal; (319u [Billings, 1861a, p. 320]) "calciferous sandrock" in the Township of Edwardstown, between Beauharnois and Lake Champlain; (392)^a at Nortons Creek; (392j)^a limestones of the "Quebec group" at Point Levis; and (392i)^a limestone at Phillipsburgh; all in the Province of Quebec, Canada.

(314c)^a Nodules of white limestone belonging to Division P of Billings's section at Cow Head, Newfoundland.

FIGURE 72.—*Syntrophia cambria* Walcott. A, A', Top view and side outline of ventral valve (U. S. Nat. Mus. Cat. No. 57029a). B, Ventral valve, the type specimen (U. S. Nat. Mus. Cat. No. 52477a). C, Dorsal valve (U. S. Nat. Mus. Cat. No. 52478). D, Partly exfoliated ventral valve (U. S. Nat. Mus. Cat. No. 52477c).

Figures 72B and 72C are copied from Walcott [1908d, Pl. X, figs. 11 and 11a]. The specimen represented by figure 72C is from Locality 34m; those represented by figures 72A, 72B, and 72D are from Locality 32e; and that represented by figure 72A is from Locality 31c, all in the Middle Cambrian of northeastern Utah.

General form transversely oval, strongly convex but not rotund. Ventral valve moderately convex, with the frontal margin in adult shells prolonged; a flattened median sinus begins on the umbo and widens to two-thirds the width of the shell in front; area unknown. Dorsal valve moderately convex except on the median fold, which is rounded but not unusually prominent; area unknown.

Surface marked by a few concentric lines of growth. The largest dorsal valve has a length of 8 mm.; width, 11 mm. A ventral valve 9 mm. in length has a width of 14 mm.

SYNTROPHIA CAMBRIA Walcott.

Text figures 72A-D.

Syntrophia cambria WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 3, pp. 106-107, Pl. X, figs. 11 and 11a. (Described and discussed as a new species. With the exception of the third paragraph the reference is copied below. Figs. 11 and 11a are copied in this monograph as figs. 72B and 72C, respectively.)

General form transversely oval, strongly convex but not rotund. Ventral valve moderately convex, with the frontal margin in adult shells prolonged; a flattened median sinus begins on the umbo and widens to two-thirds the width of the shell in front; area unknown. Dorsal valve moderately convex except on the median fold, which is rounded but not unusually prominent; area unknown.

Surface marked by a few concentric lines of growth. The largest dorsal valve has a length of 8 mm.; width, 11 mm. A ventral valve 9 mm. in length has a width of 14 mm.

^a Billings, 1865a, p. 220.

Observations.—In form this species is usually most nearly related to *Syntrophia calcifera* (Billings) (Pl. CIV, figs. 1, 1a-i). It differs in having a less clearly defined beak and less prominent fold on the dorsal valve. There are many points in common between *Syntrophia cambria* and *S. nundina* Walcott (Pl. CII, figs. 4, 4a-c), but they differ in the shorter beak and sharper median fold of the latter. *Syntrophia cambria* occurs in the Wasatch range, about 4,500 feet below the base of the Ordovician, while *S. calcifera* and *S. nundina* occur in the Lower Ordovician. It is the oldest species of the genus and is of interest also on account of being closely related in form to the Ordovician species mentioned.

FORMATION AND LOCALITY.—**Middle Cambrian:** (31c and 54o) 900 feet (274.3 m.) above the Brigham quartzite and 3,300 feet (1,005.8 m.) below the Upper Cambrian, in the limestone forming 1b of the Ute limestone [Walcott, 1908f, p. 196], in Blacksmith Fork Canyon, about 10 miles (16.1 km.) east of Hyrum, Cache County; (32e) *the same stratigraphic horizon as Locality 31c just south of the south fork of Paradise Dry Canyon (East Fork), east of Paradise, Cache County;* and (34m) limestone about 765 feet (233.2 m.) above the Brigham quartzite [Walcott, 1908a, p. 8], 1 mile (1.6 km.) northwest of Geneva (Copenhagen), east of Brigham, Boxelder County; all in Utah.

SYNTROPHIA CAMPBELLI Walcott.

Text figures 73A-F.

Syntrophia campbelli WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 3, pp. 107-108, Pl. X, figs. 9, 9a-c. (Described and discussed as below as a new species. Figs. 9, 9a-c are copied in this monograph as figs. 73B, 73C, 73E, and 73F, respectively.)

General form rotund, unequally biconvex; hinge line short. Ventral valve moderately convex, exclusive of the prolonged frontal margin; it is depressed toward the front in adult

FIGURE 73.—*Syntrophia campbelli* Walcott. A, Ventral valve, the type specimen (U. S. Nat. Mus. Cat. No. 52480f). B, Cast of ventral valve, showing cast of septum supporting the spondylium (U. S. Nat. Mus. Cat. No. 52480a). C, C', Dorsal valve (U. S. Nat. Mus. Cat. No. 52480b). D, Dorsal valve (U. S. Nat. Mus. Cat. No. 52480e). E, Section of ventral valve, showing cast of septum and spondylium (U. S. Nat. Mus. Cat. No. 52480c). F, Cast of dorsal valve, showing cast of spondylium (U. S. Nat. Mus. Cat. No. 52480d).

The specimens represented are from Locality 12q, Upper Cambrian, near Rogersville, Tennessee. Figures 73B, 73C, 73E, and 73F are copied from Walcott [1908d, Pl. X, figs. 9, 9a-c, respectively].

shells by a broad median sinus that disappears on the umbo; area short and divided midway by a relatively large, open, triangular delthyrium. Dorsal valve convex with an elevated, relatively narrow median fold that does not extend back to the beak; area short and divided by a strong, open, triangular delthyrium.

Surface marked by concentric striæ and a few strong lines of growth. The largest shell is represented by a dorsal valve that has a length of 12 mm.; width, 14 mm. A ventral valve 7 mm. in length has a width of 11 mm.

Casts of the ventral valve show a spondylium supported on a septum that extended from the beak about one-third the distance to the front margin. The spondylium of the dorsal valve rests directly on the interior of the shell without trace of a supporting median septum.

Observations.—The young shells of this species are almost evenly convex, the fold of the dorsal valve and the sinus of the ventral valve of the adult shell not having developed. The characteristic spondylium of each valve is shown in the youngest shells observed. The general form of *Syntrophia campbelli* is much like that of *Syntrophia rotundata* Walcott (Pl. CIII, figs. 4, 4a-c) and somewhat like that of *Huenella texana* (Walcott) (Pl. CIII, figs. 1, 1a-g). It differs from the former in having the spondylium of the dorsal valve resting on the interior of the shell and not supported on a septum, in this respect resembling the spondylium of *Huenella texana* (Walcott) (Pl. CIII, figs. 1h, 1i). Some shells have a somewhat transverse posterior margin like that of *H. texana*, but the larger number have the broadly acuminate outline of *S. rotundata*. The muscle scars of the dorsal valve, as far as known, are similar to those of *Huenella abnormis* (Walcott) (Pl. CIII, figs. 2i, 2s).

The specific name was given in honor of Mr. M. R. Campbell of the United States Geological Survey, who collected the specimens.

FORMATION AND LOCALITY.—**Upper Cambrian:** (12q) Knox dolomite, on Bunker Hill, 6 miles (9.6 km.) northeast of Rogersville [Keith, 1905, areal geology sheet], Hawkins County, Tennessee.

SYNTROPHIA LATERALIS (Whitfield).

Text figure 11, page 299; Plate CII, figures 6, 6a-g.

- Triplesia lateralis* WHITFIELD, 1886, Bull. Am. Mus. Nat. Hist. No. 8, p. 303, Pl. XXIV, figs. 9-11. (Described as a new species.)
- Syntrophia lateralis* (Whitfield), HALL and CLARKE, 1892, Nat. Hist. New York, Paleontology, vol. 8, pt. 1, footnote, p. 270. (Generic reference changed.)
- Syntrophia lateralis* (Whitfield), HALL and CLARKE, 1893, idem, vol. 8, pt. 2, p. 217, Pl. LXII, figs. 1-10. (Described, giving on p. 216 the footnote referred to in the preceding reference. The description of this species is copied in this monograph, under the genus *Syntrophia*. Figs. 9 and 10 are copied in this monograph, Pl. CII, figs. 6f and 6g, respectively.)
- Syntrophia lateralis* (Whitfield), HALL and CLARKE, 1894, Thirteenth Ann. Rept. State Geologist New York for 1893, vol. 2, pp. 836-837, Pl. XLV, figs. 7-12. (Copy of the description given on p. 217 of the preceding reference. Figs. 7-12 are copied from Hall and Clarke, 1893b, Pl. LXII, figs. 1, 2, 6, 9, 5, and 10, respectively.)

I have illustrated a few of the shells representing the species that, taken with those of Hall and Clarke in part 2 of volume 8 of their great work, illustrate about all that is known of *S. lateralis*. (See p. 798 for a copy of Hall and Clarke's description of the species.)

FORMATION AND LOCALITY.—**Lower Ordovician:** (227) Limestone near Fort Cassin, Addison County, Vermont.

SYNTROPHIA NUNDINA Walcott.

Plate CII, figures 4, 4a-d.

- Triplesia calcifera* WALCOTT [not BILLINGS], 1884, Mon. U. S. Geol. Survey, vol. 8, pp. 75-76, Pl. XI, figs. 7 and 8. (Characterized. The specimens represented by figs. 7 and 8 are redrawn in this monograph, Pl. CII, figs. 4 and 4a, respectively.)
- Syntrophia nundina* WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 292. (Characterized as below as a new species.)
- Syntrophia calcifera* Walcott, GRABAU and SHIMER, 1907, North American Index Fossils, vol. 1, p. 271, figs. 325. (Described. The two figures in fig. 325 are copied from Walcott, 1884b, Pl. XI, figs. 7 and 8, respectively.)

The nonplicate, convex species that is found in the Lower Ordovician of the western United States has usually been referred to *Camerella* or *Triplesia calcifera*. It is much like the latter but differs in being less convex, with apex of valves less pointed and incurved.

FORMATION AND LOCALITY.—**Lower Ordovician:** Pogonip limestone at the following localities: (63) Northeast of Adams Hill; (201a) east slope of the ridge east of Hamburg Ridge; (203) on spur on ridge extending southwest from Wood Cone; (204) on the lower part of the eastern slope of the ridge east of Hamburg Ridge, facing Secret Canyon road; and (209) on the west side of Goodwin Canyon; all in the Eureka district [Hague, 1892, Atlas], Eureka County, Nevada.

(185z) Limestones at the base of the Lower Ordovician [Walcott, 1908f, p. 191], in Blacksmith Fork Canyon, about 9 miles (14.4 km.) east of Hyrum, Cache County, Utah.

(186 and 186a) Near line of contact between red and gray Ordovician limestone, in red siliceous limestone, 30 to 35 feet (9.1 to 10.7 m.) above the pre-Cambrian rocks, Williams Canyon, Manitou, El Paso County, Colorado.

Upper Cambrian: (54b) About 1,200 feet (365.8 m.) above the Middle Cambrian and 25 feet (7.6 m.) below the top of the Upper Cambrian in the upper part of the limestone forming 1 of the St. Charles formation [Walcott, 1908f,

p. 191]; and (54c) about 1,100 feet (335.3 m.) above the Middle Cambrian and 120 feet (36.6 m.) below the top of the Upper Cambrian in the central part of the limestone forming 1 of the St. Charles formation [Walcott, 1908f, p. 192]; both in Blacksmith Fork Canyon about 10 miles (16.1 km.) east of Hyrum, Cache County, Utah.

A specimen (Pl. CII, fig. 4d) that is somewhat doubtfully referred to this species occurs at the following locality:

Upper Cambrian: (329a) Limestone on Ute Peak, in the Wasatch Mountains east of Cache Valley, Cache County, Utah.

SYNTROPHIA ORTHIA Walcott.

Plate CIV, figures 4, 4a-b.

Syntrophia orthia WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 29, pp. 11-12. (Described and discussed as a new species.)

General form irregularly oval, with the ventral view obtusely angular toward the apex; rounded, biconvex, with a deep mesial sinus on the ventral valve and a strong median fold on the anterior half of the dorsal valve. Surface smooth, with the exception of a few concentric striæ and lines of growth. The ventral valve has a strong median sinus that occupies about one-third of the width of the valve at the anterior margin and projects forward to fit into the sinus in the front of the margin of the dorsal valve; the sides of the median sinus are elevated, and with the downward-sloping lateral slopes form a strong, rounded ridge on each side of the sinus; none of the specimens in the collection show the area, but from the profile of the valve it must have been of moderate height, with a rather sharp apex curving over it.

Dorsal valve with a minute apex, from which a narrow, slightly developed median fold extends to about the posterior fourth of the shell, where it becomes elevated, and, widening, extends forward to the front margin; the remaining portions of the surface are uniformly convex, sloping away from the median fold to the margins of the valve.

Nothing is known of the interior of either valve.

Observations.—In general form this species resembles *Syntrophia primordialis* (Whitfield) of the "St. Croix sandstone" of Wisconsin. It differs in its more rounded, irregularly oval form and the very large median sinus of the ventral valve.

FORMATION AND LOCALITY.—**Upper Cambrian:** (C54) Lower part of the Chaumitien limestone [Blackwelder, 1907a, p. 42 (part of last list of fossils)], 0.66 mile (1.1 km.) west of Tsinan; (C56) same horizon as Locality C54 at Pagoda Hill [Blackwelder, 1907a, p. 42 (part of last list of fossils)], 1 mile (1.6 km.) west of Tsinan; and (C64) upper limestone member of the Kiulung group [Blackwelder, 1907a, pp. 37 and 42 (first list of fossils), and fig. 10 (bed 20), p. 38], 2.7 miles (4.3 km.) southwest of Yenchuang, Sintai district; all in Shantung, China.

SYNTROPHIA PRIMORDIALIS (Whitfield).

Plate CII, figures 2, 2a-e.

Triplexia primordialis WHITFIELD, 1878, Ann. Rept. Wisconsin Geol. Survey for 1877, p. 51. (Described.)

Triplexia primordialis WHITFIELD, 1882, Geol. Wisconsin, vol. 4, pt. 3, p. 172, Pl. X, figs. 1 and 2. (Described and discussed, the first paragraph being copied below.)

Triplexia? primordialis Whitfield, HALL and CLARKE, 1892, Nat. Hist. New York, Paleontology, vol. 8, pt. 1, p. 270, footnote. (Questions generic reference.)

Syntrophia primordialis (Whitfield), HALL and CLARKE, 1893, idem, pt. 2, p. 218. (Changes generic reference.)

Syntrophia primordialis (Whitfield), WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 292. (Whitfield's description, 1882, p. 172, copied and species discussed as below.)

The description by Whitfield [1882, p. 172] follows:

Shell small, measuring less than half an inch in width; transversely oval in outline, and quite ventricose in profile; hinge line straight and about half as long as the width of the shell below; area narrow. Ventral valve with a strongly depressed, rather narrow and rounded mesial sinus. Dorsal valve with a narrow, sharply elevated fold not extending quite to the beak; sides of the valve rounded. Surface smooth in the casts, but presenting the appearance of having been externally striate. Processes in the interior of the dorsal valve apparently forming a small spoon-shaped pit at the beak.

Observations.—Casts of the interior show the form of the spondylium and supporting median septum in the ventral valve; also, a small short spondylium in the ventral valve, which appears to be attached to the bottom of the valve without a median septum.

This species differs from *Syntrophia barabuensis* (Winchell) in its smaller size, less transverse outline, and more pronounced mesial depression on the ventral valve. Some specimens of the dorsal valves of the two species are very similar. These are shown by Plate CII, figures 1f and 2c. Some of the shells approach certain forms of *S. calcifera*, but the larger number are less convex and more transverse and with more obtuse cardinal angles. A shell closely allied to *S. primordialis*, and apparently identical, occurs in the limestone of the Reagan sandstone of Oklahoma. Only the exterior is known.

FORMATION AND LOCALITY.—Upper Cambrian: “St. Croix sandstone” at the following localities: (99) Minneiska (Miniska), on Mississippi River, near the line between Wabasha and Winona counties; (339d) Taylors Falls, Chisago County; (84a) at River Junction, Houston County, 20 miles (32.2 km.) below Dresbach, and (339g) just below the *Dikellocephalus minnesotensis* beds, near Winona, Winona County; all in Minnesota.

(328k) “St. Croix sandstone” at Roche à Cris Bluff, Adams County, Wisconsin.

(9u) About 195 feet (59.4 m.) above the porphyry contact in the limestones of the Reagan sandstone, in SE. $\frac{1}{4}$ NE. $\frac{1}{4}$ sec. 2, T. 4 N., R. 13 W., 15 miles (24.2 km.) northwest of Fort Sill, Comanche County; and (12n) limestones of the Reagan sandstone (in the section 7 miles (11.2 km.) north of Springer this horizon is about 240 feet (73 m.) above the porphyry contact and 40 feet (12 m.) below the Arbuckle limestone), NW. $\frac{1}{4}$ sec. 1, T. 2 S., R. 1 E., Ardmore quadrangle (U. S. Geol. Survey), Carter County; both in Oklahoma.

(168) Limestones on north side of Tepee Creek, near the road from Sheridan to Dome Lake, Bighorn Mountains, Sheridan County, Wyoming.

SYNTROPHIA PRIMORDIALIS ARGIA Walcott.

Plate CII, figure 3.

Syntrophia primordialis argia WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 293. (Characterized as below as a new variety.)

This specimen is separated as a variety of *Syntrophia primordialis* (Whitfield) on account of its less convexity and more shallow median sinus, which has three rudimentary plications in it.

FORMATION AND LOCALITY.—Upper Cambrian: (97) “St. Croix sandstone” at Reads Landing, foot of Lake Pepin, Wabasha County, Minnesota.

SYNTROPHIA ROTUNDATA Walcott.

Plate CIII, figures 4, 4a-e.

Syntrophia rotundata WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 293-294. (Described and discussed as below as a new species.)

General form rotund, unequally biconvex; hinge line short. Surface marked by fine, concentric striæ and low, imbricating varices of growth. The largest shell observed has a width of 13 mm.; length, 11 mm. Ventral valve convex at the umbo and beak, but depressed toward the front by a strong, broad, and deep median sinus. Area low, short, and divided midway by a relatively large triangular delthyrium. Transverse sections of the umbo near the beak show the cross section of a well-developed spondylium supported on a median septum. Dorsal valve about as convex as the ventral on the umbo, but the strong, broad median fold makes it strongly convex. Cross sections at the umbo show a spondylium and supporting septum very much like that in the ventral valve.

Observations.—This species is taken as the Cambrian representative of the genus *Syntrophia*. It has a spondylium in each valve supported by a median septum in the same manner as in the Ordovician type of the genus *S. lateralis*. Its rotund form, deep ventral sinus, and strong dorsal fold serve to distinguish *S. rotundata* from other species of the genus.

FORMATION AND LOCALITY.—Upper Cambrian: (14k) Limestone on Wolf Creek, 15 miles (24.2 km.) west-southwest of Sheridan, Bighorn Mountains, Sheridan County, Wyoming.

SYNTROPHIA? UNXIA Walcott.

Text figure 74, page 805.

Syntrophia? unxia WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 3, pp. 108-109, Pl. X, fig. 10. (Discussed as below as a new species. Fig. 10 is copied on p. 805 as fig. 74.)

This species is represented by a single specimen of the ventral valve from which the shell has been removed by weathering. The cast of the spondylium shows it to have been

of the same type as that of the ventral valve of *Syntrophia primordialis* (Whitfield) (Pl. CII, figs. 2, 2a-b) and *S. barabuensis* (Winchell) (Pl. CII, figs. 1, 1a-d). The elongate, rounded form and scarcely perceptible median sinus serve to distinguish this species from all described forms.

This is the oldest shell of this type known to me. It occurs 5,525 feet below the summit of the Cambrian, in the House Range section. I am not fully satisfied with the generic reference, but with the data available it can not well be referred to *Billingsella* or any other known genus of the Cambrian Brachiopoda.

FORMATION AND LOCALITY.—Middle Cambrian: (3x) About 2,200 feet (670.6 m.) above the Lower Cambrian and 2,200 feet (670.6 m.) below the Upper Cambrian, in the limestones forming 1d of the Marjum limestone [Walcott, 1908f, p. 180], 2.5 miles (4 km.) east of Antelope Springs, in ridge east of Wheeler Amphitheater, House Range [Walcott, 1908f, Pls. XIII and XV], Millard County, Utah.

Genus **HUENELLA** Walcott.^a

Syntrophia WALCOTT (in part) [not HALL and CLARKE], 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 288-289. (Described and discussed essentially as on p. 798 (under *Syntrophia*), but some of the species included in the genus are now referred to *Huenella*.)

Huenella WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 3, p. 109. (Characterized and discussed as below as a new genus.)

Huenella WALCOTT, 1908, idem, No. 4, Pl. XI, and pp. 142 and 148. (Classification of genus.)

This genus is proposed to include the more or less plicate species of the Syntrophiidæ that have heretofore been referred by me to the genus *Syntrophia*. They differ from *Syntrophia* in having a more or less radially plicate surface and sessile or pseudospondylia instead of free spondylia supported by a median septum. With the exception of *Huenella vermontana* and possibly *H. etheridgei*, all of the species are from the Upper Cambrian.

The shell structure is fibrous, with many minute pores.

Type.—*Syntrophia texana* Walcott [1905a, p. 294].

The generic name is given in recognition of the thorough and valuable work of Dr. Fr. von Hoenning-Huene on the "Silurischen Craniaden."

HUENELLA ABNORMIS (Walcott).

Text figure 13, page 299; Plate CIII, figures 2, 2a-m.

Not *Camerella calcifera* BILLINGS, 1861, Canadian Naturalist, 1st ser., vol. 6, No. 4, p. 318. (Referred in this monograph to *Syntrophia calcifera*.)

Camerella calcifera MEEK [not BILLINGS], 1873, Sixth Ann. Rept. U. S. Geol. and Geog. Survey Terr. (for 1872), p. 464 and footnote. (Characterized.)

Syntrophia abnormis WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 289-290. (Described and discussed as below as a new species.)

The general form varies from transverse (Pl. CIII, fig. 2) to elongate (fig. 2c). Valves biconvex, with dorsal very convex in some specimens. Hinge line straight. Surface marked by concentric striæ and imbricating lines of growth crossed by fine, rounded, radiating striæ and a variable number of rounded ribs; specimens occur with four ribs in the sinus of the ventral valve and four on each slope outside the sinus; in other ventral valves only a trace of ribs can be seen; among the specimens of the dorsal valve there are shells without a sign of ribs, figure 2d, and others having from a trace of ribs on the median fold to three ribs on the fold and traces on the lateral slopes. The largest shell has a length of 7 mm.; width, 9 mm. There is great variation in the proportion of the length to the width, as shown by the figures illustrating the species.

FIGURE 74.—*Syntrophia? unzia* Walcott. Ventral valve, the type specimen, from which the shell has been entirely removed by weathering (U. S. Nat. Mus. Cat. No. 52499). From Locality 3x, in the Middle Cambrian, House Range, Utah. Copied from Walcott [1908d, Pl. X, fig. 10].

^a Prior to the definition of the genus *Huenella* the species now referred to that genus were described under the following genera:

Camerella Shumard [1861, p. 221].
Camerella Meek [1873, p. 464].

Orthis or *Orthisina* Etheridge [1905, p. 250].
Syntrophia Walcott [1905a, p. 288].

The ventral valve has a broad, strong sinus that depresses the front of the valve; area well defined, with a large, open delthyrium. Casts of the interior of the ventral valve show a well-marked spondylium and very strong main vascular sinuses, figure 2b; both spondylium and sinuses recall those of *Billingsella plicatella* (Pl. LXXXVI, figs. 3g, 3j). Sections of the ventral valve, cut across the umbo, show the spondylium attached to the bottom of the valve. The flabelliform diductor and adductor muscle scars are clearly shown outside of the vascular sinuses.

Dorsal valve with an elevated median fold that gives a strong convexity to the valve; area low, with a strong, open delthyrium; the interior of the valve shows a shallow spondylium attached to the bottom of the valve posteriorly, and probably supported by a low median septum toward the front (figs. 2i, 2j, section fig. 2m) and well-defined anterior and posterior adductor muscle scars; narrow main vascular sinuses occur (fig. 2h), and slender vascular lines radiate forward from the muscle scars (fig. 2f).

Observations.—This species differs from all allied forms in its variation in outline, convexity, ribs, and internal markings. Some shells approach closely to those of *Huenella texana* (Walcott) (compare figs. 1 and 2 and figs. 1b and 2a, Pl. CIII), but each species has a majority of shells that are quite unlike those of the other. Another point of resemblance is the form of the spondylium as shown by cross sections. A variety of *H. texana* from Cold Creek Canyon, Texas, has some shells that approach those of *H. abnormis* in the extravagant development of the fold on the dorsal valve and sinus on the ventral valve, but in other respects they differ from it. The form of spondylium and plications or ribs suggests the genus *Parastrophia* Hall.

This form was an abnormal representative of the genus *Syntrophia*, to which it was first referred, hence the specific name.

FORMATION AND LOCALITY.—Upper Cambrian: (153) Limestone in ravine on west side of Dry Creek, near the mouth of Pass Creek, about 5 miles (8 km.) north of Hillsdale; and (157 and 158) limestone north of East Gallatin River, near Hillsdale; both on the Threeforks quadrangle (U. S. Geol. Survey), Gallatin County, Montana.

(302p) Middle limestone of the Deadwood formation, near the summit of the Owl Creek Mountains, 18 miles (29 km.) southwest of Thermopolis, Fremont County, Wyoming.

Middle Cambrian: (4j) Limestone at the head of Deep Creek, Yellowstone National Park, Canyon quadrangle (U. S. Geol. Survey), Wyoming.

HUENELLA BILLINGSI (Walcott).

Plate CII, figures 5, 5a-c.

Syntrophia billingsi WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 291-292. (Described and discussed as below as a new species.)

General form transversely subquadrate; rounded; biconvex, with the dorsal valve elevated on the median fold. Surface marked by a few imperfectly developed ribs on some shells, while others have only concentric striæ and lines of growth. Ventral valve with a relatively shallow median sinus, in which obscure, narrow ribs sometimes occur; none of the specimens in the collection show the area, but from the profile of the valve it must have been of moderate height, with the rather sharp apex curving slightly over it; a single poor cast of the interior shows the outline of a spondylium much like that of *S. primordialis*; the evidence of the presence of a median septum is a dark line in front of the end of the cast of the spondylium, which indicates that the shell substance extends down into the limestone and that it is the median septum. Dorsal valve with a small umbo and apex that extend forward into a prominent median fold that may be plicated (Pl. CII, fig. 5c) or smooth; one partly exfoliated shell shows three plications on the fold and three or four on each lateral slope of the valve.

Observations.—This species belongs to the plicate group of the Syntrophiidæ represented by *Huenella texana* (Walcott) and *H. abnormis* (Walcott). It differs from *H. texana* in being less convex and in having a shallower ventral sinus, less prominent dorsal fold, and more obscure plications.

The specific name was given in honor of Mr. E. Billings.

FORMATION AND LOCALITY.—Middle? Cambrian: (28a) "St. Albans formation," in limestone lentil about 1 mile (1.6 km.) east of Parker's quarry, west of Georgia, Franklin County, Vermont.

HUENELLA ETHERIDGEI Walcott.

Plate LXXXIX, figures 9, 9a.

Orthis (or *Orthisina*) sp. ETHERIDGE, 1905, Trans. Roy. Soc. South Australia, vol. 29, p. 250, Pl. XXV, figs. 9 and 10. (Described as below and discussed. The specimens represented by figs. 9 and 10 are redrawn in this monograph, Pl. LXXXIX, figs. 9 and 9a, respectively.)

Huenella etheridgei WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 3, pp. 109-110, Pl. X, figs. 13 and 13a. (Described and discussed as below, copying the original descriptions. Figs. 13 and 13a are drawn from the specimens represented by figs. 9 and 10 of the preceding reference and are copied in this monograph, Pl. LXXXIX, figs. 9a and 9, respectively.)

Doctor Etheridge describes the ventral valve as follows:

Subquadrilateral, convex, the greatest convexity at about midway in the length of the valve, the sinus gradually deepening and widening toward the front, and bounded laterally by ill-defined folds, one on either side, the surface sloping away on either side rapidly to the lateral margins, and at a very much less angle within the sulcus; there are indications of costæ on the divaricating folds and in the sulcus.

The hinge features are hidden in matrix, nor is the umbo distinctly visible.

He describes the dorsal valve as follows:

Rotundato-quadrate, the cardinal margin as long as the width of the valve, the surface convex, except on the dorso-lateral alations, where it appears to be flattened. There is a central, acute, or pinched-up fold, produced forward, and expanding as it advances. There are indications of the existence of strong, distinct, subradiating costæ.

Whether or no this is the brachial valve of the species represented by the preceding form it is at present impossible to say; the two occur in the same bed, however.

From the study of the various forms of *Huenella* described herein, I think that the two valves belong to one species, and I take pleasure in naming it after Dr. R. Etheridge, jr.

FORMATION AND LOCALITY.—Middle? Cambrian: (315c [Etheridge, 1905, p. 250]) "Archæocyathinæ white limestone" at Wirrialpa, Flinders Range, South Australia.

HUENELLA LESLEYI Walcott.

Text figures 75A-C.

Huenella lesleyi WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 3, p. 110, Pl. X, figs. 12 and 12a. (Characterized and discussed as below as a new species. Figs. 12 and 12a are copied in this monograph as figs. 75B and 75A, respectively.)

Only the exterior of the valves of this species is known. In form and outline it is most nearly related to *Huenella texana* (Walcott). It differs from the latter in being broader in proportion to its length, and in having narrow, radiating, rounded ribs over the entire surface.

FIGURE 75.—*Huenella lesleyi* Walcott. A, A', Exterior of partly exfoliated dorsal valve (U. S. Nat. Mus. Cat. No. 52481b). B, Exterior of ventral valve, the type specimen (U. S. Nat. Mus. Cat. No. 52481a). C, Exterior of ventral valve (U. S. Nat. Mus. Cat. No. 52481c).

The specimens represented are from Locality 54e in Blacksmith Fork Canyon, Cache County, Utah. Figures 75A and 75B are copied from Walcott [1908d, Pl. X, figs. 12a and 12, respectively].

This is probably the oldest *Huenella*. It occurs 1,025 feet (312.4 m.) below the summit of the Upper Cambrian. *Billingsella coloradoensis* (Shumard) and *Lingulella manticula* (White) occur in the same bed of limestone.

The specific name is given in honor of the late Dr. J. P. Lesley, state geologist of Pennsylvania.

FORMATION AND LOCALITY.—Upper Cambrian: (54e) About 200 feet (61 m.) above the Middle Cambrian and 1,025 feet (212.4 m.) below the top of the Upper Cambrian in limestones forming 3 of the St. Charles formation [Walcott, 1908f, p. 193], in Blacksmith Fork Canyon, about 10 miles (16.1 km.) east of Hyrum, Cache County, Utah.

HUENELLA ORIENTALIS (Walcott).

Plate CIV. figures 3, 3a-b.

Syntrophia orientalis WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 292. (Characterized and discussed as below as a new species.)

This species is closely related in form and surface characters to *Huenella texana* (Walcott) and some forms of *H. abnormis* (Walcott). It differs from them in details of surface ribs. On the dorsal valve there are two or three faintly defined radiating ribs on each side of the median fold, which has obscure ribs upon it. Corresponding ribs occur upon the mesial depression of the ventral valve and the side slopes adjoining the depression. The material representing it is too limited to warrant an identification with any described species. *H. orientalis* is the trans-Pacific representative of *H. texana*.

FORMATION AND LOCALITY.—Upper Cambrian: (C64) Upper limestone member of the Kiulung group [Blackwelder, 1907a, pp. 37 and 42 (first list of fossils), and fig. 10 (bed 20), p. 38] 2.7 miles (4.3 km.) southwest of Yenchiung, Sintai district, Shantung, China.

HUENELLA TEXANA (Walcott).

Plate CIII, figures 1, 1a-i.

Camerella sp.? SHUMARD, 1861, Am. Jour. Sci., 2d ser., vol. 32, p. 221. (Mentioned; see below for copy.)

Syntrophia texana WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, p. 294. (Original mention copied and species discussed as below as a new species.)

This may be called the plicate representative of the group of species referred to the Syntrophiidae. It is intimately connected with the smooth forms by a series of shells that vary from 16 ribs on a valve to 1; the extremes are shown by Plate CIII, figures 1d and 1e. In form *H. texana* is much like *H. abnormis* (Walcott); also in the cross section of its spondylium. They differ in the extravagant development of the plications of *H. texana*, a feature characteristic of a large series of specimens.

The average size of the larger shell is width, 8 mm.; length, 6 to 7 mm.

It is probable that this is the shell referred to by Dr. Shumard [1861, p. 221] as *Camerella* sp.?. He said of it:

There are several specimens of a small brachiopod in the Texas state collection, from the Potsdam sandstone of Morgans Creek, Burnet County, which appear to belong to the genus *Camerella* recently created by Mr. E. Billings. Unfortunately, however, they consist merely of detached and imperfect valves too much weathered for satisfactory determination and description.

FORMATION AND LOCALITY.—Upper Cambrian: (68) *Interbedded sandstone and limestone, Packsaddle Mountain, Llano County*; (71) limestone in Cold Creek Canyon, Burnet County; and (69) limestone near Honey Creek, Burnet County: all in Texas.

HUENELLA TEXANA LEVIUSCULUS (Walcott).

Syntrophia texana leviusculus WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 294-295. (Characterized and discussed as below as a new variety.)

A variety occurs in Texas with a few traces of plication in the sinus: and with one, two, or three strong plications on the dorsal fold, or none at all; it approaches *Huenella abnormis* (Walcott) in some of its extreme forms where the ribs are large on a prominent mesial fold. In most young shells the sinus and fold are inconspicuous, the convexity is very moderate, and the shell smooth; nearly all the characters of the adult are missing.

A group of young shells from Honey Creek shows only the smooth, slightly convex forms, with only slight ventral sinus and dorsal fold. One larger shell associated with the young shells has a relatively deep sinus and a trace of a plication.

FORMATION AND LOCALITY.—Upper Cambrian: (69) Limestone near Honey Creek; and (71) limestone in Cold Creek Canyon; both in Burnet County, Texas.

HUENELLA VERMONTANA n. sp.

Text figure 76.

This species is represented by a single specimen of the two valves united. It is somewhat imperfect near the beaks.

Valves moderately and about equally convex, with the dorsal valve subcircular in outline and the ventral more elongated at the beak. Hinge short; cardinal angles rounded.

Surface marked by low, concentric ridges of growth and numerous fine, rounded, radiating ridges that increase in number from the umbo to the margin by both bifurcation and interpolation of new ridges. A low, moderately broad sinus occurs on the anterior half of the ventral valve and a narrow median fold on the dorsal valve. Where the surface of the shell is exfoliated the shell appears to be minutely punctate.

The ventral valve has a length of 11 mm.; width, 9 mm. The convexity of the two valves is 6 mm.

Observations.—This shell differs from all known species of *Huenella* by its finely ribbed surface. In this respect it recalls *Swantonina antiquata* (Billings) (Pl. CIV, fig. 5). It occurs in association with *Paradoxides* in an intraformational conglomerate.

FORMATION AND LOCALITY.—Middle Cambrian: (319s) "St. Albans formation," at St. Albans, Franklin County, Vermont.

Genus CLARKELLA Walcott.^a

Clarkella WALCOTT, 1908, Smithsonian Misc. Coll., vol. 53, No. 3, pp. 110-111. (Described and discussed as below as a new genus.)

Clarkella WALCOTT, 1908, idem, vol. 53, No. 4, Pl. XI, and pp. 142 and 148. (Classification of genus.)

General form rotund, unequally biconvex. Surface smooth or marked by concentric striæ and lines of growth. Ventral valve convex at the umbo and with a strong, broad median sinus; area low and divided by a relatively large delthyrium. Dorsal valve convex at the umbo, which is extended forward into a strong, broad median fold. Cross sections of the valves near the apex and beneath the umbo show a spondylium supported by four or more septa that divide the umbonal cavity into five chambers.

Thin sections of the shell of the type species show it to be fibrous and with many minute pores arranged in lines radiating from the beak to the front and side margins of the valves.

Type.—*Polytachia? montanensis* Walcott.

This genus is known only by the type species from the Lower Ordovician of Montana. It is distinguished from *Polytachia* Hall and Clarke [1892c, p. 239] by an open delthyrium, smooth surface, and presence of septa and spondylium in the dorsal valve. It differs from *Syntrophia* and *Huenella* in having several septa supporting the spondylium, and also from *Huenella* in having a smooth nonplicate surface.

The generic name is given in recognition of the work of Prof. John M. Clarke, of the Geological Survey of New York, in connection with Prof. James Hall, on the fossil Brachiopoda.

FIGURE 76.—*Huenella vermontana* n. sp. A, Ventral view of a specimen. A', Dorsal view of same specimen. A'', Side view of the same specimen, showing the two valves united.

The specimen is from Locality 319s, near St. Albans, Vermont (U. S. Nat. Mus. Cat. No. 58312).

^a Prior to the definition of the genus *Clarkella* the type species was placed under *Polytachia* [Walcott, 1903a, p. 293].

CLARKELLA MONTANENSIS (Walcott).

Plate CIV, figures 2, 2a-d.

Polytarchia? montanensis WALCOTT, 1905, Proc. U. S. Nat. Mus., vol. 28, pp. 295-296. (Characterized and discussed as below as a new species.)

This shell was placed with *Camerella calcifera* until sections were made showing the numerous septa supporting the spondylium and cruralium. In general form it is close to *Syntrophia rotundata* Walcott, differing in the numerous supporting septa of the spondylium which divide the umbonal cavity into five chambers. The material available for study does not show the area in very good preservation; a delthyrium exists in the area of the ventral valve, which is all that can be said.

This species appears to be a direct descendant of the smooth, convex forms of *Syntrophia*, like *S. rotundata*.

FORMATION AND LOCALITY.—Lower Ordovician: (302j) Limestone on the east side of West Gallatin (Gallatin) River, above Gallatin, Gallatin County, Montana.

INDEX.

In this index **black-face** figures refer to locality numbers, light-face figures refer to pages. The *main reference* to each genus and species (the page reference which is usually put in black-face type under the old scheme of lumping all references together, or the page reference which will be used in the future synonymy of the genus or species) is given first and is invariably preceded by the word "described," even if the genus or species is little more than mentioned on the page given.

References to the description of certain features of a species or to comparisons with other species are indexed only if the description or comparison occurs on some other page than the one on which the species is described.

The table of synonymic references, on pages 27-98, may be regarded as a completely cross-referenced index to the synonymy in the monograph, as each name in that table is there given in the form in which it appears in the synonymy of the species to which it is now referred. This index therefore includes only those synonymic references that appear in connection with the description of the genera and species, all synonyms being placed in quotation marks.

This index gives the numbers of all the localities in any country, province, State, county, district, or place, as well as the numbers of all the localities identified from the different formations or other stratigraphic units. These numbers are tabulated on pages 160-291, where full information is given as to species included, authority for citation, correlation and comparison with other localities, and the stratigraphic section (pp. 123-159) in which the locality is placed or with which it is correlated. For these reasons this index includes no reference to the localities given in connection with the description of the species. The names of species given under the heading "Localities," on pages 160-291, are not indexed as appearing on those pages, but the page on which each brachiopod there named is described appears in the index, and on this page are given not only the numbers but detailed descriptions of all localities from which the species has been identified.

Geographic names that have been passed on by the United States Geographic Board are spelled in accordance with that board's decisions, but a few variant familiar spellings have been inserted in the index with cross references.

 Acrotreta idahoensis 633
 Acrotreta sagittalis toconica 633
 general geographic and stratigraphic distribution tabulated 105
 in group based on surface characteristics 632
 surface ornamentation discussed 302
 type specimen figured Pl. LX, fig. 1
Acrothele subsidua hera, described 659
 general geographic and stratigraphic distribution tabulated 105
 in group based on surface characteristics 632
 type specimen figured Pl. LX, fig. 9
subsidua lævis, described 659
 compared with *Acrothele subsidua* 658
 general geographic and stratigraphic distribution tabulated 105
 in group based on surface characteristics 632
 type specimen not figured.
turneri, described 660
 general geographic and stratigraphic distribution tabulated 105
 in group based on surface characteristics 632
 type specimen figured Pl. LX, fig. 7
villoboimensis, described 660
 general geographic and stratigraphic distribution tabulated 105
 in group based on surface characteristics 633
 type specimen not figured.
woodworthi, described 661
 compared with *Acrothele spurri* 656
 general geographic and stratigraphic distribution tabulated 105
 in group based on surface characteristics 632
 stratigraphic position mentioned 318
 type specimen figured Pl. LX, fig. 6
yorkensis, described 661
 compared with *Acrothele* sp. undt. a 662
 general geographic and stratigraphic distribution tabulated 105
 in group based on surface characteristics 633
 type specimen figured Pl. LXIII, fig. 5
 sp. undt. Moberg, described 662
 general geographic and stratigraphic distribution tabulated 105
 in group based on surface characteristics 633
Acrothele (Redlichella), described 662
 cardinal area discussed 305
 classification of 321, 324
 evolution of 317
 general geographic and stratigraphic distribution of the species referred to 105
 general stratigraphic distribution and number of Cambrian species and varieties of 111
 intermediate between *Botsfordia* and *Acrothele* 663
 number of species of, in different types of sediment 160
 type species "*Acrothele granulata*" 632, 663
granulata, described 663
 compared with *Acrothele bella punctata* 637
 Acrothele bohémica 639
 Acrothele coriacea 643
 Acrothele intermedia 646
 Acrothele matthewi 632, 648
 Acrothele panderi 651
 Acrothele rara 655
 Acrothele subsidua 658
 Acrothele yorkensis 662
 Botsfordia granulata 602
 general geographic and stratigraphic distribution tabulated 105
 intermediate between *Acrothele coriacea* and *Botsfordia granulata* 663
 surface of, confused with that of *Acrotreta socialis* 712
 surface ornamentation discussed 302
 type specimen not figured.
 Acrothelinae, classification of 321, 324
 genera and species referred to, described 630-665
Acrothyra, described 715
 cardinal area discussed 305
 classification of 321, 324
 compared with *Acrothele* and *Acrotreta* 313
 Acrotreta? cancellata 679
 Discinopsis 721

- Acrotreta claytoni*, described..... 680
 general geographic and stratigraphic distribution tabulated..... 105
 surface features mentioned..... 672
 type specimen figured..... Pl. LXXIV, fig. 3
concentrica, described..... 681
 general geographic and stratigraphic distribution tabulated..... 105
 type specimen figured..... Pl. LXXVII, fig. 1
conula, described..... 681
 general geographic and stratigraphic distribution tabulated..... 106
 type specimen figured..... Pl. LXXV, fig. 2b
convexa, described..... 682
 compared with *Acrotreta gemmula*..... 686
 general geographic and stratigraphic distribution tabulated..... 106
 type specimen figured..... Pl. LXVI, fig. 6
 “? *costata*,” discussed..... 674
curvata, described..... 682
 cardinal area discussed..... 305
 compared with *Acrotreta idahoensis*..... 688
Acrotreta microscopica..... 693
Acrotreta ophirensis..... 697
Acrotreta sagittalis transversa..... 673
Acrotreta ulrichi..... 714
 general geographic and stratigraphic distribution tabulated..... 106
 type specimen figured..... Pl. LXVIII, fig. 1a
definita, described..... 683
 cardinal area discussed..... 305
 compared with *Acrotreta bellatula*..... 678
Acrothele bellula..... 631, 637
Acrotreta rudis..... 702
 general geographic and stratigraphic distribution tabulated..... 106
 type specimen figured..... Pl. LXIV, fig. 2c
depressa, described..... 683
 compared with *Acrotreta definita*..... 683
Acrotreta rudis..... 702
 general geographic and stratigraphic distribution tabulated..... 106
 type specimen figured..... Pl. LXVI, fig. 8
eggegrundensis, described..... 684
 general geographic and stratigraphic distribution tabulated..... 106
 stratigraphic position of bowlder containing..... 454, 864
 type specimen figured..... Pl. LXX, figs. 2a-c
emmonsii, described..... 684
 general geographic and stratigraphic distribution tabulated..... 106
 stratigraphic position mentioned..... 318
 type specimen figured..... Pl. LXV, fig. 6
gemma?, described..... 685
 compared with *Acrotreta depressa*..... 683, 684
Acrotreta ovalis..... 699
Acrotreta schmalensei..... 709
 discussed..... 673
 general geographic and stratigraphic distribution tabulated..... 106
 mentioned..... 675, 691
 species referred to mentioned..... 673, 689
 type specimen figured..... Pl. LXVI, fig. 1
gemmula, described..... 686
 compared with *Acrothyra proavia*..... 717
Obolus (Westonia) ella..... 674
 general geographic and stratigraphic distribution tabulated..... 106
 type specimen figured..... Pl. LXVI, fig. 3a
gracia, described..... 687
 general geographic and stratigraphic distribution tabulated..... 106
 type specimen figured..... Pl. LXVI, fig. 5a
 “? *guelicmi*,” type of *Discinopsis*..... 720
idahoensis, described..... 687
 compared with *Acrothele subsidua*..... 633
Acrotreta argenta..... 674
Acrotreta curvata..... 682
Acrotreta definita..... 683
- Acrotreta idahoensis*—Continued.
 compared with *Acrotreta eggegrundensis*..... 648
Acrotreta emmonsii..... 684

- Bronsil shales (Upper Cambrian), in generalized section for England, Scotland, and Wales, listing species and localities 135
- localities in 304, 304a
- Brown’s quarry, Prairie du Sac, Wisconsin, locality at 85a
- Bruachaig River, Scotland, locality on 316c
- Brunswick, New York, locality near 2d
- Bryn Melyn, North Wales, locality at 366o
- Bryogroptus* slate (Upper Cambrian), in generalized section for Sweden, Denmark, Finland, and Norway, listing species and localities 145
- locality in 309a
- systematic reference discussed 98
- Buch, C. L. von, bibliographic references 14
- Buchava quarry, near Skřej, Bohemia, locality at 345d
- buchi*, see *Keyserlingia*.
- Buck Creek, Alabama, locality near 56c
- Buckingham Ford on Hollis Creek, Tennessee, locality at 117e
- Buffalo County, Wisconsin, locality in 328c
- Buffalo Creek, Montana, locality near 302f
- Buffalo Creek, Virginia, locality on 92b
- Buffalo Fork Peak, Wyoming, locality near 302v
- Buffalo Mills, Virginia, locality near 92b
- Builth, Wales, locality near 366r
- Bull Hill Cottage, South Shropshire, England, locality at 304k
- Bull Run, Tennessee, localities in 107, 107a, 107b
- Bullwhacker mine, Eureka district, Nevada, locality near 64
- Bunker Hill, Tennessee, locality on 12q
- Burgess, Canada, locality at 392
- Burgess Pass, British Columbia, locality near 35k
- Burgess shale, mentioned 127
- Burgess shale member of the Stephen formation (Middle Cambrian), locality in 35k
- Burling, Lancaster D., acknowledgments 13
- work on Cambro-Ordovician boundary in British Columbia 125
- Burling, Mrs. Lancaster D., species named for 758
- Burnet, Texas, localities near 67, 67c, 67z
- Burnet County, Texas, localities in 67,
- 67c, 67z, 69, 70, 70a, 70e, 71, 353a
- Burr, H. T., bibliographic reference 15
- Butts, Charles, species named for 484
- buttsi*, see *Lingulella*.
- Caballos Mountains, New Mexico, localities in 327, 327a-c
- Cable Mountain, Montana, locality on 340e
- Cabo Busto stage (Ordovician), localities in 350a, 350b
- Cache County, Utah, localities in 31c-e,
- 31h, 31 l-n, 31z, 32d, 32e, 54a-p, 54y, 55b, 55n, 55t, 185z, 329a
- calata*, see *Botsfordia*.
- Caer-fai, Wales, locality at 366c
- Caerfai group (Middle Cambrian), in generalized section for England, Scotland, and Wales, listing species and localities 136
- localities in 318l, 366c
- Cairn Burn, Scotland, locality at 316b
- calcifera*, see *Syntrophia*.
- “Calciferous sandrock” (Lower Ordovician), *Lingulella (Lingulepis) acuminata* in, discussed 547
- localities in 319t, 319u, 338u
- mentioned 509
- “Calciferous sandstone,” mentioned 551
- Caledonia, Missouri, locality near 369d
- California, Cambrian species of, listed 114-119
- localities in 7, 8b, 14 l, 14n-p, 53, 176, 176a, 178a, 312, 312a
- species and localities correlated with those of Nevada 137-138
- Callaway, C., bibliographic references 15
- Calls Fort, Utah, locality near 329
- Camarella*, compared with *Swantonia* 797
- “*calcifera*,” compared with *Clarkella montanensis* 810
- compared with *Stricklandinia* 798
- mentioned 798
- volborthi*, compared with *Swantonia antiquata* 797
- cambrina*, see *Schuchertina* and *Syntrophia*.
- Cambrian, number of genera in divisions of 316
- sedimentation in Cordilleran region mentioned 148
- species of Asia, zoologic list of, giving distribution by countries 121-122
- species of Europe, zoologic list of, giving distribution by countries 120-121
- species of North America, zoologic list of, giving geographic distribution by States and geologic provinces 114-119
- See also Lower, Middle, and Upper Cambrian, and Passage beds.
- Cambridge, New York, localities near 36, 338x
- Cambridge quadrangle, New York, localities in 21
- 33, 33b, 36, 36b, 37, 37b, 39a, 43, 43a,
- 45a, 338c-g, 338l, 338 l, 338o, 338p, 338x
- Camarella*, mentioned 802
- “*antiqua*,” type of *Swantonia* 797
- “sp. Shumard” discussed 808
- Camlan, North Wales, locality at 318e
- Campbell, M. R., bibliographic reference 15
- species named for 802
- campbelli*, see *Syntrophia*.
- Camp Creek Canyon, see Queens Canyon.

- Division C1c of Matthew (Middle Cambrian), in generalized section for Cape Breton, listing included species and localities 132
localities in 301g, 301h, 301m, 301w, 301z, 308b
- Division C1d of Matthew (Middle Cambrian), in generalized section for Cape Breton, listing included species and localities 132
localities in 300, 3011
- Division C2a of Matthew (Middle Cambrian), in generalized section for Cape Breton, listing included and correlated species and localities 132
locality in 307f
- Division C2b of Matthew (Middle Cambrian), in generalized section for Cape Breton, listing included and correlated species and localities 132
localities in 31, 307g
- Division C2c of Matthew (Middle Cambrian), in generalized section for Cape Breton, listing included and correlated species and localities 131
localities in 301x, 301y, 307c?
- Division C3a of Matthew (Upper Cambrian), in generalized section for Cape Breton, listing included and correlated species and localities 131
localities in 10r?, 301e, 301n, 301t, 308a, 308b, 308f, 325b
- Division C3b of Matthew (Upper Cambrian), in generalized section for Cape Breton, listing included and correlated species and localities 131
localities in 301u, 307e, 307h, 307i, 307j, 325
- Division C3c of Matthew (Upper Cambrian), in generalized section for Cape Breton, listing included and correlated species and localities 131
localities in 307, 307e, 307h, 307j, 308
- Division C3c2 of Matthew (Upper Cambrian), in generalized section for Cape Breton, listing included species and localities 131
locality in 307a
- Division E is the Etcheminian, which also see for lists of localities.
- Division E1a, in detailed section on Dugald Brook, Cape Breton 134
- Division E1b of Matthew (Middle Cambrian), in detailed section on Dugald Brook, Cape Breton, listing included species and localities 134
localities in 13t, 13t', 344k
- Division E1c of Matthew (Middle Cambrian), in detailed section on Dugald Brook, Cape Breton, listing included species and localities 134
localities in 13t'', 344g
- Division E1d of Matthew (Middle Cambrian), in detailed section on Dugald Brook, Cape Breton, listing included and correlated species and localities 134
localities in 13t'', 344e, 344m
- Division E1e of Matthew (Middle Cambrian), in detailed section on Dugald Brook, Cape Breton, listing included species and localities 134
locality in 344h
- Division E2a of Matthew (Middle Cambrian), in detailed section on Dugald Brook, Cape Breton, listing included and correlated species and localities 134
localities in 13d, 13d', 13d'', 13i, 13g, 13p, 13p', 307d
- Division E2b of Matthew (Middle Cambrian), in detailed section on Dugald Brook, Cape Breton, listing included and correlated species and localities 134
localities in 10p, 10q, 13d, 13d', 344o
- Division E2c of Matthew (Middle Cambrian), in detailed section on Dugald Brook, Cape Breton, listing included species and localities 134
localities in 13e, 344i
- Division E3a of Matthew (Middle Cambrian), in detailed section on Dugald Brook, Cape Breton, listing included species and localities 133
localities in 131, 131', 3441
- Division E3b of Matthew (Middle Cambrian), in detailed section on Dugald Brook, Cape Breton, listing included species and localities 133
locality in 344
- Division E3c of Matthew (Middle Cambrian), in detailed section on Dugald Brook, Cape Breton, listing included species and localities 133
locality in 344a
- Division E3d of Matthew (Middle Cambrian), in detailed section on Dugald Brook, Cape Breton, listing included and correlated species and localities 133
localities in 13n'', 344b, 344c
- Division E3e of Matthew (Middle Cambrian), in detailed section on Dugald Brook, Cape Breton, listing included and correlated species and localities 133
localities in 13n', 344j
- Division E3f of Matthew (Middle Cambrian), in detailed section on Dngald Brook, Cape Breton, listing included and correlated species and localities 133
localities in 13m, 13n, 344d
- Division P of Billings (Lower Ordovician), localities in 314c, 314d
See also Quebec group.
- Division 2 of Matthew (Upper Cambrian), locality in 2x
- Division 3e (?) of Matthew (Lower Ordovician), locality in 301s
- Djunpadal, Sweden, localities in 320a, 320n
- Clouhâ Hora, Bohemia, locality on 345
- Dobbs Linn, Scotland, locality at 316
- Dodson Ford, Tennessee, localities near 103a, 103b
dolatus, see *Obolus*.
- Dolgelly, North Wales, localities near 318, 318c, 318f, 366g, 366h
- Dolgelly group, in generalized section for England, Scotland, and Wales, listing species and localities 135
- Dome Canyon, House Range, Utah, localities in 11w,
30c, 30d, 30e, 31s, 31v
- Dome Canyon limestone, in detailed section in House Range, Utah, listing included and correlated species and localities 157
- Dome Lake, Bigborn Mountains, Wyoming, locality near 168
- Domgint, Esthonia, Russia, locality at 396d
- doris*, see *Eoorthis*.
- Dorsal valve, defined 293
reasons for preservation of, in *Trematobolus* 617
- Down (County), Ireland, locality in 317
- Dresbach, Minnesota, localities at 84, 84f
- Drinkwater mine, Silver Peak quadrangle, Nevada, locality near 1v
- Druidhill Burn, Scotland, locality at 316b
- Dry Creek, Montana, localities on 150a, 152a, 152b, 153, 153a, 154
- Dryton, England, locality at 304i
- dubia*, see *Lingulella* and *Siphonotricta*.
- Dublin (County), Ireland, locality in 317a
- Dugald Brook, Cape Breton, detailed section of Middle Cambrian on, listing included and correlated species and localities 133-134
localities on 10p, 10q,
13d, 13d', 13d'', 13e-g, 13k, 13l, 13l', 13n, 13n', 13n'', 13p, 13p',
13t, 13t', 13t'', 344, 344a, 344b, 344d, 344f-1, 344k-m, 344o, 372f
- dugaldensis*, see *Protorthis* (*Loperia*).
- Dugway Range, Utah, locality in 32t
- Dumfriesshire, Scotland, localities in 316, 316b
- Dunderberg mine, Eureka district, Nevada, locality near 66
- Dunderberg shale (Upper Cambrian), detailed section, listing included and correlated species and localities 139
localities in 61, 62, 66
mentioned 688, 689
- Dunn County, Wisconsin, localities in 79a, 80, 82a, 100, 134, 134a
- Dunns shore, New Brunswick, locality at 301x
- Dutchess County, New York, *Lingulella* (*Lingulepis*) *acuminata* in, discussed 548
localities in 32, 108, 367d, 367e, 367j
- Dwight, W. B., bibliographic references 16
- Eagle Mills, New York, locality near 338y
- Eakles Mills, Maryland, localities at 16f, 47f
- East Bay, Cape Breton, localities on 10r, 131, 13q, 307j, 325, 325b, 372d
- East Braintree, Massachusetts, locality at 326b
- East Canyon, Oquirrh Range, Utah, locality in 329c
- East Fork, see Paradise Dry Canyon
- East Gallatin River, Montana, localities on or near 4g,
4h, 155, 155a, 156a, 156b, 157, 158, 158a
- Easton Station, New York, localities near 39a, 3381
- East Point, Nahant, Massachusetts, locality at 326g
- East Prussia, localities in 386, 386a-c, 386i-k
localities in, correlated with those of Russia 143
- Eau Claire, Wisconsin, localities near 78a, 98, 98x
- Eau Claire County, Wisconsin, localities in 78a, 98, 98x
- Echinosphærites* limestone—C1 (Ordovician), in generalized section for Russia, listing species and localities 143
localities in 336, 336v, 386i-1
- "Edgewise beds" (Upper Cambrian), in generalized section for Missouri, listing species and localities 137
localities in (see p. 137) 11k, 369a
referred to the Upper Cambrian 137
- Edson, George, species named for 328
edsoni, see *Rustella*.

- Edwardstown, Quebec, locality in 319n
Egan Canyon, Egan Range, Nevada, locality in 8f
Egan Range, Nevada, locality in 8f
Egeberg, Norway, locality at 323v
Eggegrund Island, Sweden, locality on 311
 stratigraphic position of boulders found on, discussed 684
egggrundensis, see *Acrotreta*.
Eichwald, C. E. von, bibliographic references 16
 species named for 390
eichwaldi, see *Obolus*.
Ekerum, Oeland Island, Sweden, localities near 310e, 310f
Elbe River, Germany, locality near 386e
Eldon limestone (Middle Cambrian), detailed section, listing included and correlated species and localities 126-127
 localities in 35g, 57n
Eldorado limestone (Middle Cambrian), detailed section, listing included and correlated species and localities 140
 localities in 54, 55, 55b, 57
elegans, see *Obolus*.
elgontula, see *Curticia* and *Eostrophomena*.
Elkania, described 561
 cardinal area discussed 304
 classification of 310, 321, 323
 compared with *Monobolina* 378, 410
 Obolus and *Obolus* (*Fordinia*) 428
 Schuchertina 585
 development of area in 561, 562
 evolution discussed 318
 evolution of 317
 general geographic and stratigraphic distribution of the species referred to 103
 Hall and Clarke on development of 309
 muscle scars discussed 312
 number of Ordovician species and varieties of 113
 number of species of, in different types of sediment 160
ambigua, described 562
 compared with *Elkania desiderata* 563
 general geographic and stratigraphic distribution tabulated 103
 platform discussed 310
 type specimen figured Pl. LI, fig. 2a
desiderata, described 562
 compared with *Dicellomus pectenoides* 575
 Elkania ambigua 562
 Elkania ida 563, 564
 Obolella 562
 Obolus 563
 Obolus apollinis 562
 Obolus (*Fordinia*) *perfectus* 430
 discussed 561
 general geographic and stratigraphic distribution tabulated 103
 platform discussed 310
 type specimen not figured.
ida, described 563
 general geographic and stratigraphic distribution tabulated 103
 platform discussed 310
 type specimen not figured.
Elkaniinae, classification of 321, 323
 genera and species referred to, described 561-564
Elk Pass, Yellowstone National Park, Montana, locality in 302f
Elk Range, Colorado, locality in 360c
ella, see *Obolus* (*Westonia*).
ella onaquiensis, see *Obolus* (*Westonia*).
Elliptocphala asaphoides, association mentioned 473, 531, 605
Elliptocphala asaphoides fauna, mentioned 594
Ells, R. W., species named for 496
ellsii, see *Lingulella*.
elongata, see *Obolella crassa*.
elongatus, see *Obolus* (*Westonia*).
El Paso County, Colorado, localities in 186,
 186a, 187, 360, 360a, 360d, 360f, 360g
El Paso County, Texas, locality in 353b
Elvins, Missouri, localities near 369a, 369c
Elvins formation (Upper Cambrian), in generalized section for Missouri, listing species and localities 137
 localities in 11 l, 369, 369d
Ely, Nevada, locality near 8p
Ely Mountains, Nevada, localities in 7k, 31
Emigrant formation (Upper Cambrian), localities in 7s,
 7v, 7x-z, 8a, 8b', 8r
 note on 137
Emigrant Pass, Nevada, localities near 7x-z, 8a, 8b'
Emigrant Peak, Nevada, localities near 7r, 7s, 7v, 8r
Emigsville, Pennsylvania, localities near 49, 49b, 49c, 49w, 346
Emmons, E., bibliographic references 16
 species named for 685
Emmons, W. H., bibliographic reference 16
emmonsii, see *Acrotreta*.
Endlich, F. M., species named for 342
endlichii, see *Micromitra sculptilis*.
Engervik, Norway, locality at 323e
England, Cambrian species of, listed 120-121
 generalized section of Cambrian and Ordovician in, listing species and localities 135-136
 localities in 304, 304a-l, 304n-p
 "*Eoobolus*," characterized 377
 synonym of *Obolus* 377
Eoorthis, classification of 321, 326
 genera and species referred to, described 772-795
 surface ornamentation discussed 303
Eoorthis, described 772
 cardinal area discussed 305
 classification of 321, 326
 compared with *Billingsella* 755
 Finkelburgia 793, 794
 Orusia 765
 cruralium mentioned 309
 evolution discussed 320
 evolution of 317
 general geographic and stratigraphic distribution of the species referred to 108, 109
 general stratigraphic distribution and number of Cambrian species and varieties of 111
 intermediate between *Billingsella* and Ordovician orthoids 773
 intermediate between *Billingsella* and *Orthis* 772
 mentioned 761
 muscle scars discussed 313
 number of Ordovician species and varieties of 113
 number of species of, in different types of sediment 160
 pseudospondylium discussed 307
 reference to, of *Eoorthis atava* discussed 774
 Eoorthis christianiae discussed 775
 Eoorthis ? diablo discussed 779
 Eoorthis johannensis discussed 782
 Eoorthis saltensis discussed 788-789
 Eoorthis sp. undt. a mentioned 792
 "*Leptana melita*" discussed 777
 "*Orthis* sp. Pompeckj" mentioned 793
 type species "*Orthis remnicha*" 773
 Ulrich on spondylium 308
 vascular markings discussed 311, 312
agrestis, described 773
 compared with *Eoorthis* sp. undt. c. 793
 general geographic and stratigraphic distribution tabulated 108
 type specimen figured Pl. LXXXIX, fig. 6
atava, described 774
 general geographic and stratigraphic distribution tabulated 108
 type specimen figured Pl. XCV, fig. 7
bavonica, described 775

| <i>Lingulella mosia osceola</i> | 521 | | |
| <i>Lingulella similis</i> | 533 | | |

- Lingulella similis*, described 532
 compared with *Lingulella desiderata* 492
Lingulella leos 514
 general geographic and stratigraphic distribution tabulated 103
 type specimen figured Pl. XXI, fig. 2
 viscera area (splanchnocoel) characterized 470
 ? *simpler*, described 534
 general geographic and stratigraphic distribution tabulated 103
 type specimen not figured.
- tarpa*, described 534
 compared with *Lingulella franklinensis* 502
Lingulella ino 507
 general geographic and stratigraphic distribution tabulated 103
 type specimen figured Pl. XXIII, fig. 2a
- tezana*, described 535
 general geographic and stratigraphic distribution tabulated 103
 type specimen figured Pl. XLIX, fig. 3a
- torrentis*, described 535
 general geographic and stratigraphic distribution tabulated 103
 type specimen figured Pl. XXXV, fig. 7
- triparilis*, described 536
 compared with *Lingulella (Lingulepis) gregwa* 556
Lingulella (Lingulepis) longinervis 556
Lingulella (Lingulepis) pumila 556
Obolus ? torrentis 418
 general geographic and stratigraphic distribution tabulated 103
 intermediate between *Lingulella (Lingulepis) gregwa* and *Lingulella (Lingulepis) longinervis* 556
 type specimen not figured.
- tumida*, described 537
 confused with *Lingulella (Lingulepis) gregwa* 537, 554
 general geographic and stratigraphic distribution tabulated 103
 type specimen not figured.
- "*unguiculus*" mentioned 497
- upis*, described 538
 compared with *Lingulella wanniecki* 538, 539
 general geographic and stratigraphic distribution tabulated 103
 type specimen figured Pl. XXXVI, fig. 3
- wanniecki*, described 538
 compared with *Lingulella fuchsi* 502
 general geographic and stratigraphic distribution tabulated 103
 type specimen not figured.
- welleri*, described 539
 general geographic and stratigraphic distribution tabulated 103
 type specimen figured Pl. XXXVIII, fig. 4
- winona*, described 539
 compared with *Lingulella winona conveza* 540
 general geographic and stratigraphic distribution tabulated 103
 grouped on the basis of the outline of the ventral valve 470
 type specimen not figured.
- winona conveza*, described 540
 compared with *Obolus pheres* 408
 general geographic and stratigraphic distribution tabulated 103
 type specimen figured Pl. XVIII, fig. 4a
- wirthi*, described 541
 compared with *Lingulella cedens* 485
 general geographic and stratigraphic distribution tabulated 103
 type specimen figured Pl. XXX, fig. 7
- zeus*, described 541
 general geographic and stratigraphic distribution tabulated 103
 type specimen figured text fig. 45, 541
- sp. undt. a, described 541
 compared with *Lingulella agnostorum* 476
 general geographic and stratigraphic distribution tabulated 103
 type specimen figured Pl. XXX, fig. 13
- Lingulella* sp. undt. b, described 541
 general geographic and stratigraphic distribution tabulated 103
 type specimen not figured.
- sp. Kayser, discussed and compared with *Lingulella davisi* and *L. ampla* 490-491
 "(?) sp. Matley," discussed 703
- Lingulella (Leptembolon)*, described 541
 characterized 473-474
 classification of 321, 323
 evolution discussed 319
 evolution of 317
 general geographic and stratigraphic distribution of the species referred to 103
 general stratigraphic distribution and number of Cambrian species and varieties of 110
 may include *Lingulella ? insons* 508
 mentioned 378
 number of species of, in different types of sediment 160
 type species "*Obolus (Leptembolon) linguleiformis*" 474
linguleiformis, described 542
 general geographic and stratigraphic distribution tabulated 103
 type specimen not figured.
- linguleiformis solidus* discussed 543
- Lingulella (Lingulepis)*, described 544
 characterized 474
 classification of 321, 323
 compared with *Botsfordia* 602
Delgadella 560
Lingulella 472
 evolution discussed 319
 evolution of 317
 general geographic and stratigraphic distribution of the species referred to 103
 general stratigraphic distribution and number of Cambrian species and varieties of 110
 mentioned 378, 471, 488, 557, 558, 559, 560, 668
 number of Ordovician species and varieties of 113
 number of species of, in different types of sediment 160
 reference to, of *Lingulella (Lingulepis) acuminata mecki*, discussed 550
 relative position of vascular sinus in species of 377
 stratigraphic distribution of species discussed 545
 surface ornamentation discussed 302
 type species "*Lingulella acuminata*" 544
 type species of, discussed 547, 548
 young shells more elongate than adult shells 473
- acuminata*, described 545
 compared with *Lingulella bornemannii* 483
Lingulella cuncola 488
Lingulella signata 532
Lingulella (Lingulepis) acuminata mecki 550
Lingulella (Lingulepis) acuminata sequens 551
Lingulella (Lingulepis) crigua 553, 555
Lingulella (Lingulepis) gregwa 555
Lingulella (Lingulepis) roberti 557
Lingulella (Lingulepis) rowci 558
Lingulella (Lingulepis) squamosa 559
Obolus chromatica 592
Obolus belli 386
Obolus rhea 411
Obolus sinoc 545
Obolus (Westonia) rogersi 464
 general geographic and stratigraphic distribution tabulated 103
 type specimen figured Pl. XL, fig. 1
- acuminata mecki*, described 550
 compared with *Delgadella lusitanica* 560
Lingulella (Lingulepis) eros 551
 general geographic and stratigraphic distribution tabulated 103
 type specimen figured Pl. XLI, fig. 2
- acuminata sequens*, described 551
 general geographic and stratigraphic distribution tabulated 103
 type specimen figured text fig. 46A, 551
- acuminata weeksi*, merely an error in spelling 550, 551
- eros*, described 551
 general geographic and stratigraphic distribution tabulated 103
 type specimen figured Pl. XXXIX, fig. 9

 Louise, see Lake Louise.
louise, see *Micromitra* (*Iphidella*).
 Lovened, Sweden, localities at 310q, 320h, 320n
 Low, A. P., species named for 734
 Low Hampton, New York, localities near 34, 39, 45b
 “Lower black slates” (Upper Cambrian), locality in 318m
- Lower Cambrian:
 Alabama, generalized section listing included and correlated species and localities 147
 Alberta, species and localities correlated with those of British Columbia 129-131
 Bohemia, localities and species in listed 124
 British Columbia, detailed section listing species and localities 129-131
 California, species and localities correlated with those of Nevada 137-138
 Cape Breton, note on its absence 135
 Denmark, generalized section listing included and correlated species and localities 146
 England, generalized section, listing species and localities 136
 families represented in, listed 112
 Finland, generalized section, listing included and correlated species and localities 146
 genera identified in, listed 110-111, 317
 Georgia, generalized section, listing included and correlated species and localities 147
 line of separation between Middle Cambrian and, in Cordilleran region 148, 153
 Nevada, detailed sections, listing included and correlated species and localities 137-138, 140
 New Brunswick, note on 135
 Newfoundland, detailed section, listing species and localities 141
 Norway, generalized section, listing included and correlated species and localities 146
 Russia, generalized section, listing species and localities 144
 Scotland, generalized section, listing species and localities 136
 species from, discussed 316, 318
 species from, listed 89-109
 Sweden, generalized section, listing included and correlated species and localities 146
 Tennessee, generalized section, listing included and correlated species and localities 147
 Utah, detailed section, listing included and correlated species and localities 158
 Wales, generalized section, listing species and localities 136
 “Lower graptolite slate” (Passage beds), locality in 390f
 “Lower lenticular layer” (“Linsenschicht”) (Passage beds), in generalized section for Russia 143
 localities in or near 396m, 396p
- Lower Stockingford shales, in generalized section for England, Scotland, and Wales, listing species and localities 135
- lowi*, see *Nisusia* (*Jamesella*).
Lucinia divaricator, surface ornamentation discussed 301
 Luga River, see Louga River.
 Lugnås, Sweden, localities at 309d, 390j
 Luh, near Skrej, Bohemia, locality at 345e
 Lumparn, Åland Island, Finland, locality near 311e
 Lumparströmmen, Åland Island, Finland, locality near 311d
 Lund, Sweden, localities near 309, 309a, 309h, 309i, 310t, 320d, 321s, 321t, 321z, 390b, 390g
- lusitanica*, see *Delgadella*.
 Lyck, East Prussia, locality near 386c
lyncoides, see *Orusia lenticularis*.
 McAdam shore, East Bay, Cape Breton, localities on 10r, 325, 372d
 McAphee’s corner, Hardingville, New Brunswick, locality at 301s
 McCodrum Brook, Cape Breton, localities on and near 3i, 344n
mcconnelli, see *Obolus*.
mcconnelli decipiens, see *Obolus*.
mcconnelli pelias, see *Obolus*.
 McCoy, F., bibliographic references 19, 20
 McGill post office, Nevada, locality near 313
 McGill’s ranch, Nevada, locality near 8p
 McGregor, Iowa, locality at 341a
 Mackenzie Basin, British Columbia, locality in 306
 McKinley Canyon, Cahallos Mountains, New Mexico, locality in 327a
 McLean Brook, Cape Breton, localities on 3i, 10s, 10t, 307f, 307g
 McLeod Brook, see Barachois River.
 McMinn County, Tennessee, locality in 128a
 McMullins Brook, Cape Breton, localities on 16o, 372e
 McMullin’s place, Cape Breton, localities near 5p, 10d, 372b
 McNaughton Corner, New York, locality at 45a
 McNeil Brook, Cape Breton, localities on and near 3h, 307i, 325a
 McPhees, Cape Breton, locality at 344j
 McPhees Brook, Cape Breton, localities on and near 10p’, 307b
 McPhees Point, see Youngs (McPhees) Point.

modesta, see *Linnarssonella*.
Moel-y-gest, North Wales, locality at 305a
Moffat, Scotland, locality near 316
Möller, V. von, bibliographic reference 21
Mona, Utah, locality near 14t
monilifera, see *Mickwitzia*.
Monobolina, compared with *Obolus* and *Elkania* 378, 410
Monobolina plumbea, discussed 410
Monomerella, Hall and Clarke on development of 309
 platform mentioned 309
Montagne Noire, France, locality in 342
Montana, Cambrian species of, listed 114-119
 localities in (Lower Cambrian) 4v, 4w, 5j
 localities in (Middle Cambrian) 3j, 4g, 4h,
 4k, 4p-g, 4n, 4x, 5f, 5k, 8j, 9h, 9k, 9m, 149a, 155a, 156a, 159,
 302, 302a, 302b, 302k, 302s-t, 302w, 302z, 340, 340a, 340e, 340f
 localities in (Ordovician) 302j
 localities in (Upper Cambrian) 4r,
 147a, 148a, 150a, 151, 151a, 152, 152a, 152b, 153, 153a, 154, 155,
 156b, 157, 158, 158a, 160, 160a, 161, 302f, 302n, 302q-r, 340b
 stratigraphic position of localities in, discussed 137
Montana, Missouri, localities near 11d, 369e
montanensis, see *Clarkella*.
Monte de Valbom, Alemtejo, Portugal, locality at 351
Montevallo, Alabama, localities near 141a, 142, 164f
"Montevallo shale" (Lower Cambrian), in generalized section for
 Tennessee, Georgia, and Alabama, listing species and lo-
 calities 147
 localities in 17b, 56c
Montpelier, Idaho, localities west of 55c, 56f, 56g, 59f, 59g, 163, 322
Montreal Island, Canada, locality on 319n
Morenci, Arizona, locality near 358
Morgan County, Utah, locality in 329c
Morgans Creek, Texas, localities on 70, 70a, 70e, 353a
Morris, J., bibliographic references 21
Morristown quadrangle, Tennessee, localities in 103a, 103b, 104, 374a
Moses Hill, near North Greenwich, New York, locality on 43
mosia, see *Lingulella*.
mosia osceola, see *Lingulella*.
Mossebo, Sweden, locality at 390f
Mountain Island, Minnesota, localities on 339e, 339i
Mount Billingen, Sweden, locality on 321p
 See also Billingen.
Mount Bosworth, Alberta, localities on 35c,
 35g, 35h, 57c, 57d, 57g, 57k, 57s, 57y, 58z
Mount Bosworth section, in detail, with included and correlated
 species and localities 125-131
Mount Delano, Montana, locality near 4r
Mount Dennis, British Columbia, locality near 58r
Mount Field, British Columbia, Burgess shale on, mentioned 127
 locality near 35k
Mount Helena, Montana, locality on 302s
Mount Holly Gap, Pennsylvania, locality at 49f
Mount Nebo Canyon, near Mona, Utah, locality in 14t
Mount Stephen, British Columbia, localities on 14s,
 35f, 57e, 57f, 57j, 57m, 57n, 57r, 58j-l, 58p, 58r, 58s
 Ogygopsis zone in discussed 127
Mount Washington, near Eau Claire, Wisconsin, locality on 78a
Mount Whyte, Alberta, locality on 35e
- Mount Whyte formation (Lower Cambrian), detailed section, list-
ing included and correlated species and localities 120-130
 localities in 35c, 35e, 35f, 35h, 57e, 57m, 57r, 57s, 58k, 58p, 58s
Mount Zion Church, near York, Pennsylvania, locality near 49e
multicostata, see *Acrotreta matthewi*.
Munkesten, Sweden, locality at 320e, 321q
Murchison, R. I., bibliographic references 22, 23
Murphrees Valley, Alabama, locality in 89
Murray, A., bibliographic reference 22
 species named for 406
murrayi, see *Obolus*.
Muscle scars, determination of 460
 discussed 312-313
Muskkrat Spring, Stansbury Range, Utah, localities near 32f,
 32g, 32j, 32k, 32o, 34u, 34v
Nahant, Massachusetts, localities at 326c, 326g
"Nahant limestone" (Lower Cambrian), locality in 326c
namouna, see *Obolus*.
Nankiang River, China, localities on C32, C32
nanno, see *Lingulella*.
Nant-y-groes, North Wales, locality near 366m
nanus, see *Dicellocum*.
Närke, see Nerike.
Narragansett Bay, Rhode Island, locality on 343
Narwa, Esthonia, Russia, localities at 336s, 336z
 localities west of 337f, 337g, 395d, 395k, 395q, 395t
Nathorst, A. G., species named for 521
nathorsti, see *Lingulella*.
Natrona County, Wyoming, locality in 302o
Natural Bridge, Virginia, locality near 47a
nautes, see *Nisusia (Jamesella)*.
Navy Island, St. John Harbor, New Brunswick, localities on 308, 308a
Neanie, defined 295
Nebo Canyon, see Mount Nebo Canyon.
neboensis, see *Acrotreta*.
Neihart, Montana, localities near 4x, 5f, 5k, 340
Neobolina, classification of 321, 323
 genera and species referred to described 564-567
Neobolus, described 564
 cardinal area discussed 304, 305
 classification of 310, 321, 323, 566
 evolution discussed 318
 evolution of 317
 general geographic and stratigraphic distribution of
 the species referred to 103
 general stratigraphic distribution and number of Cam-
 brian species and varieties of 110
 Hall and Clarke on development of 309
 number of species of, in different types of sediment 160
 platform mentioned 309
 warthi, described 566
 o compared with *Obolus apollinis* 564
 discussed 566
 general geographic and stratigraphic distribution tabu-
 lated 103
 type specimen figured Pl. LXXXI, fig. 2f
 "wynnei," discussed 567
Neobolus beds (Middle Cambrian), localities in 357, 357a-c
Neotremata, cardinal area discussed 304-305
 classification of 321, 323
 defined 294
 distribution in Cambrian strata 316
 evolution of genera of, discussed 319
 holoperipheral growth of pseudodeltidium in 306
 muscle scars compared with those of *Obolus* 312, 313
 muscle scars discussed 312-313
 pedicle tube discussed 314-315
 surface ornamentation discussed 302
 vascular markings discussed 311
Nepionic, defined 294
Nerike, Sweden, localities in 320n, 320v, 320z
Neuhof, Germany, locality at 303f
Nevada, Barrel Spring section, in detail, listing included and cor-
related species and localities 137-138
 Cambrian species of, listed 114-119
 detailed section of Cambrian and Ordovician in, listing in-
 cluded and correlated species and localities 139-140
 detailed section of Lower Cambrian in, listing included and
 correlated species and localities 137-138

Nevada—Continued.
 Eureka district section, in detail, listing included and correlated species and localities..... 139-140
 note on Middle and Upper Cambrian localities in..... 137
 localities in..... 11-m, 1p, 1v, 41, 71-k, 7n, 7r, 7s, 7v, 7x, 7y, 7z, 8a, 8b', 8c, 8f, 8m-p, 8r, 10w, 14m, 30, 31, 31a, 31u, 52, 54, 55, 55b, 56, 57, 57b, 58, 59, 60, 61, 62, 62a, 63, 64, 65, 66, 174c, 175, 184, 201, 201a, 202, 203, 203a, 204, 205, 206a, 209, 211, 214a, 214b, 216a, 221, 313, 313a-k, 333, 333a-b
 species and localities in, compared with those of Utah..... 153-158
 Nevado de Castillo, Argentina, locality at..... 389a
 Newberry, J. S., species named for..... 784
newberryi, see *Eoarthris*.

 Nisusia festinata 729
 Nisusia (Jamesella) perpasta macra 736
 Nisusia (Jamesella) perpasta subquadrata 736, 737
 general geographic and stratigraphic distribution tabulated 107
 type specimen not figured.
perpasta macra, described 736
 general geographic and stratigraphic distribution tabulated 107
 type specimen figured Pl. CI, fig. 3a
perpasta subquadrata, described 736
 general geographic and stratigraphic distribution tabulated 107
 type specimen figured Pl. CI, fig. 2a
spencei, described 737
 general geographic and stratigraphic distribution tabulated 107
 type specimen figured Pl. XCIII, fig. 7a
utahensis, described 737
 general geographic and stratigraphic distribution tabulated 107
 type specimen figured Pl. CI, figs. 10 and 10a
 sp. undt., described 738
 general geographic and stratigraphic distribution tabulated 107
 type specimen not figured.
 Nisustinae, classification of 321, 325
 genera and species referred to, described 725-745
 surface ornamentation discussed 303
nitens, see *Linnarssonella*.
nitida, see *Acrothele*.
 Nøersnæs, Norway, locality at 9f
 Noetling, F., bibliographic references 22
 Nolichucky shale (Middle Cambrian), in generalized section for Tennessee, Georgia, and Alabama, listing species and localities 147
 localities in 2z, 124, 124a, 374c

 Obolacea, classification of 321, 322
 distribution in Cambrian strata 316
 genera and species referred to described 369-378
Obolella, described 586
 articulating processes discussed 307
 cardinal area discussed 304, 305
 classification of 321, 324
 compared with *Acrotreta argenta* 673, 674
 Acrotreta emmonsii 684
 Bicia 569
 Botsfordia 602
 Dicellomus 572, 577, 592
 Elkania 562
 Elkania desiderata 562
 Kutorgina 582
 Lingulella 471, 472, 473
 Lingulella prima 527
 Linnarssonella 314
 Obolella (Glyptias) favosa 600
 Obolus 312, 376, 592
 Pentamerus 597
 Quebecia 611
 Trematobolus 615, 616
 Trematobolus kempanum 620
 Yorkia? washingtonensis 613
 development mentioned 562
 evolution discussed 319
 evolution of 317
 general geographic and stratigraphic distribution of the species referred to 104
 general stratigraphic distribution and number of Cambrian species and varieties of 110
 Hall and Clarke on development of 309
 mentioned 373, 386, 388, 389, 392, 403, 423, 471, 472, 650
 muscle scars discussed 312
 number of species of, in the different types of sediment 160
 pedicle tube discussed 314
 reference of *Obolella asiatica* to, discussed 589
 shell structure 297
 stratigraphic position mentioned 318
 surface ornamentation discussed 302
 vascular markings discussed 311
asiatica, described 588
 general geographic and stratigraphic distribution tabulated 104
 type specimen figured Pl. LV, fig. 6
atlantica, described 589
 compared with *Acrotreta bellula* 637
 Lingulella acutangula 590
 Linnarssonella 314
 Linnarssonella tennessensis 669
 Obolella chromatica 591, 592
 Obolella crassa 593
 Obolella minor 597
 Obolella mobergi 598
 Obolus? zoppi 422
 discussed 587
 general geographic and stratigraphic distribution tabulated 104
 type specimen figured Pl. LV, fig. 1h
chromatica, described 591
 compared with *Dicellomus politus* 572
 Kutorgina 579
 Obolella atlantica 590
 Obolella crassa 593
 Obolella mobergi 598
 Quebecia circe 610
 general geographic and stratigraphic distribution tabulated 104
 type specimen not figured.

- Obolus*, sp. undt. f.—Continued.
- general geographic and stratigraphic distribution tabulated 100
- type specimen figured Pl. XV, fig. 9
- sp. undt. g, described 423
- general geographic and stratigraphic distribution tabulated 100
- type specimen not figured.
- Obolus* conglomerate, in generalized section for Russia, listing species and localities 144
- mentioned 419
- Obolus* conglomerate (Upper Cambrian), localities from sandstone below 395m-r
- Obolus* conglomerate (Upper Cambrian), localities in 9e, 336l, 390l, 395f-l, 395s-u
- Obolus* sandstone (Upper Cambrian), in generalized section for Russia, listing species and localities 143
- in generalized section for Sweden, Denmark, Finland, and Norway, listing species and localities 145
- localities in 9d, 310n, 311v, 311w, 321, 321a-d, 321o, 336a-c, 336j-m, 336r-u, 395, 395a-e, 395z
- mentioned 390, 391, 408, 413
- Obolus* (*Acritis*), described 437
- characterized 377
- classification of 321, 323
- compared with "*Euobolus*," "*Schmidtia*," and "*Thysanotos*" by Mickwitz 434
- evolution of 317
- general geographic and stratigraphic distribution of the species referred to 101
- general stratigraphic distribution and number of Cambrian species and varieties of 110
- mentioned 427, 441
- number of species of, in different types of sediment 160
- stratigraphic range mentioned 379
- surface ornamentation discussed 301
- type species "*Obolus* (*Lucina*) *antiquissimus*" 377, 437
- antiquissimus*, described 437
- compared with *Obolus obscurus* 407
- Obolus* (*Acritis*?) *rugatus* 441
- Obolus* (*Mickwitzella*) *siluricus* 435, 436
- Obolus* (*Palæobolus*) 426
- Obolus* (*Palæobolus*) *bretonensis* 427
- "*Obolus* (*Thysanotos*) *siluricus*" 377-378
- general geographic and stratigraphic distribution tabulated 101
- type specimen not figured.
- rugatus*, described 441
- compared with *Obolus obscurus* 407
- evolution discussed 318
- general geographic and stratigraphic distribution tabulated 101
- type specimen figured Pl. XIII, fig. 2
- Obolus* (*Bröggeria*), described 424
- characterized 377
- classification of 321, 323
- evolution discussed 318
- evolution of 317
- general geographic and stratigraphic distribution of the species referred to 101
- general stratigraphic distribution and number of Cambrian species and varieties of 110
- number of species of, in different types of sediment 160
- stratigraphic range mentioned 379
- type species "*Obolella salteri*" 377, 424
- salteri*, described 424
- compared with *Obolus* sp. undt. a 422
- general geographic and stratigraphic distribution tabulated 101
- type specimen figured Pl. XV, fig. 4
- "*Obolus* (*Euobolus*) *discus*," discussed 536
- figured 536
- "*Obolus* (*Euobolus*)," species and varieties recognized by Mickwitz, listed 380
- Obolus* (*Fordinia*), described 428
- characterized 378
- classification of 310, 321, 323
- development 310
- evolution discussed 318
- evolution of 317
- Obolus* (*Fordinia*)—Continued.
- general geographic and stratigraphic distribution of the species referred to 101
- general stratigraphic distribution and number of Cambrian species and varieties of 110
- intermediate between *Obolus* and *Elkania* 428
- muscle scars discussed 312
- number of species of, in different types of sediment 160
- stratigraphic range mentioned 379
- type species *Obolus* (*Fordinia*) *perfectus* 378, 428
- bellulus*, described 428
- compared with *Obolus apollinus* 562
- Obolus* (*Fordinia*) *gilberti* 428, 429
- Obolus* (*Fordinia*) *perfectus* 428, 430
- general geographic and stratigraphic distribution tabulated 101
- platform mentioned 310
- type specimen figured Pl. LI, fig. 3d
- gilberti*, described 429
- compared with *Obolus* (*Fordinia*) *bellulus* 428, 429
- Obolus* (*Fordinia*) *perfectus* 428, 430
- confused with *Dicclomus politus* 429
- general geographic and stratigraphic distribution tabulated 101
- platform mentioned 310
- type specimen figured Pl. LI, fig. 5
- perfectus*, described 429
- compared with *Lingulella clarki* 485
- Obolus* (*Fordinia*) *bellulus* 428
- Obolus* (*Fordinia*) *gilberti* 428, 429
- development of 310
- general geographic and stratigraphic distribution tabulated 101
- intermediate between *Obolus apollinus* and *Elkania desiderata* 310
- muscle scars in, discussed 310
- platform discussed 310
- type of *Obolus* (*Fordinia*) 378, 428
- type specimen figured Pl. LXIII, fig. 10a
- "*Obolus* (*Leptembolon*) *lingulaformis*," type of *Lingulella* (*Leptembolon*) 474
- "*Obolus* (*Lingulella*) *bicensis*," discussed 605
- Obolus* (*Lingulobolus*), described 430
- characterized 378
- classification of 321, 323
- compared with *Lingulella* 432, 472
- Obolus* 433, 434
- evolution discussed 318
- evolution of 317
- general geographic and stratigraphic distribution of the species referred to 101
- mentioned 379, 471
- number of Ordovician species and varieties of 113
- number of species of, in different types of sediment 160
- old-age characters discussed 315
- stratigraphic range mentioned 379
- surface ornamentation discussed 302
- type species *Lingulella* ? *affinis* 378, 431
- affinis*, described 431
- compared with *Obolus feistmanteli* 392
- general geographic and stratigraphic distribution tabulated 101
- type specimen not figured.
- spissus*, described 432
- compared with *Acrotreta idahoensis* 688
- Obolella crassa* 594
- Obolus* (*Lingulobolus*) *affinis* 432
- general geographic and stratigraphic distribution tabulated 101
- type specimen not figured.
- "*Obolus* (*Lucina*) *antiquissimus*," type of *Obolus* (*Acritis*) 377, 437
- Obolus* (*Mickwitzella*), described 434
- characterized 378
- classification 321, 323
- compared with *Obolus* (*Acritis*) 437
- evolution discussed 318
- evolution of 317
- general geographic and stratigraphic distribution of the species referred to 101

 localities in 8z, 310c, 310p, 320l, 323b
 cf. *tessini*, association mentioned 531
tessini zone (Middle Cambrian), in generalized section for Sweden, Denmark, Finland, and Norway, listing species and localities 146
 localities in 310m, 310o, 320d, 320h, 320o, 334c
 Parara, Yorke Peninsula, South Australia, locality at 315a
Parastrophia, reference to, of *Hucnella abnormis* discussed 806
 Parietal band, defined 294
 shown in figure 374
 Paris, Idaho, locality near 322a
 Park County, Montana, localities in 4r, 148a
 Parker's quarry, near Georgia, Vermont, localities at and near 25, 28a, 319g, 319j, 319k, 319m
 Parks, W. A., acknowledgments 12
parvula, see *Acrotreta*.
parvus, see *Dicclomus* and *Obolus*.
 Passage beds, Bohemia, localities and species in, listed. Denmark, generalized section, listing included and correlated species and localities 144
 families in, listed 112
 Passage beds—Continued.
 Finland, generalized section, listing included and correlated species and localities 144
 genera in, listed 110-111
 Nevada, detailed section, listing species and localities 139
 Norway, generalized section, listing included and correlated species and localities 144
 Russia, generalized section, listing species and localities 143
 species in, listed 98-109
 Sweden, generalized section, listing included and correlated species and localities 144
 Pass Creek, Montana, localities on and near 150a, 152a, 152b, 153, 153a, 154
Patella rivulosa, type of *Philebra* 724
 "Paterina," *Rustella* compared with Beecher's ideal 328
 type of Beecher's genus discussed 334, 344, 349
 used as a subgenus 336, 344
 (*Paterina*), see *Micromitra* (*Paterina*).
 Paterinidae, classification of 321, 322
 distribution in Cambrian strata 316
 genera and species referred to, described 329-369
 general stratigraphic distribution and number of Cambrian genera and species of 112
 number of Cambrian genera and species of 112
 number of genera and species in monograph 113
 number of Ordovician genera and species in monograph 113
 vascular markings discussed 311
 Patterson Canyon, Schell Creek Range, Nevada, locality in 8e
 Pavant Mountains, Utah, localities in 331, 33n
 Pawlowski, near St. Petersburg, Russia, localities at 336w, 395w
 Peak, Tennessee, locality near 7d
 Peale, A. C., bibliographic reference 22
 species named for 339
pealti, see *Micromitra*.
pectenoides, see *Dicclomus*.
peculiaris, see *Kutorgina*.
 Pedicle, defined 294
 Pedicle aperture, discussed 314-315
 Pedicle furrow, defined 294
 shown in figure 374
 Pedicle groove, defined 294
 Pedicle muscles, defined 294
 Pedicle muscle scar, shown in figure 374
 Pedicle opening, defined 295
 development of 306
 discussed 318
 Pedicle tube, defined 295
 development of 314
 discussed 314-315
pelias, see *Obolus mcconnelli*.
pellico, see *Nisusia* (*Jamesella*).
 Peltier, Tennessee, locality near 374e
Peltura fauna, C3b (Upper Cambrian), locality in 325
Peltura zone, in generalized section for Cape Breton, listing included and correlated species and localities 131
 Pembrokehire, South Wales, locality in 366
 Penmain Pool, North Wales, locality at 318
 Penmorfa, North Wales, locality at 366k
 Penmorfa Church, North Wales, locality at 318t
 Pennsylvania, Cambrian species of, listed. localities in 8q, 12v, 48d, 49, 49a-f, 49w, 50, 50a, 346, 346a-c
 note on stratigraphic position of localities in 143
 Penrhyn quarries, Middle Granville, New York, locality at 22a
 Pentameracea, classification of 321, 326
 eruralium mentioned 309
 distribution in Cambrian strata 316
 genera and species referred to, described 796-810
 microscopic structure of Cambrian and later, discussed 300
 Pentamerida, Ulrich on spondylium 308
Pentamerus, compared with *Obolella* 597
 Ulrich on spondylium 308
 Pen-y-Bryn, North Wales, locality at 366h
 Pen-y-pleidian, South Wales, localities at 318g, 318j
 Pepin, see Lake Pepin.
 Pepper Mountains, Poland, locality in 368
perattenuata, see *Lingulella*.
perfectus, see *Obolus* (*Fordinia*).
 Peripheral vascular canals, shown in figure 374
perpasta, see *Nisusia* (*Jamesella*).
perpasta macra, see *Nisusia* (*Jamesella*).

- perpasta subquadrata*, see *Nisusia (Jamesella)*.
perugata, see *Kutorgina*.
 Peterson, Utah, locality near..... 329c
 Pewardine, England, locality at..... 304k
phaon, see *Lingulella*.
pheres, see *Obolus*.
Philhedra, described..... 724
 cardinal area, discussed..... 305
 classification of..... 321, 325
 evolution of..... 317
 general geographic and stratigraphic distribution of the species referred to..... 107
 general stratigraphic distribution and number of Cambrian species and varieties of..... 111
 muscle scars, not shown in..... 313
 number of species of, in different types of sediment..... 160
 occurrence in Cambrian, discussed..... 319
 type species "*Patella rivulosa*"..... 724
columbiana, described..... 724
 general geographic and stratigraphic distribution tabulated..... 107
 type specimen figured..... Pl. LXXXI, fig. 10
 Phillips, J., bibliographic reference..... 22
 species named for..... 352
 Phillipsburgh, Quebec, localities at..... 392i, 392m
 Phillipsburgh formation (Lower Ordovician), mentioned..... 319f
 Phillipsburg quadrangle, Montana, localities in..... 302q, 302r, 340e
phillipsi, see *Micromitra (Paterina)*.
Pholidops implicata, compared with *Bicia whitcavessi*..... 568
Phyllograptus slate (Passage beds), in generalized section for Sweden, Denmark, Finland, and Norway, listing species and localities..... 144
 localities in..... 323, 323i
 Pike View, near Colorado Springs, Colorado, locality near..... 360d
pileolus, see *Orbiculoidea*.
 Pilot Knob, Wisconsin, locality near..... 99a
 Pinal County, Arizona, locality in..... 358a
 Pinnacle Peak, Eureka district, Nevada, locality near..... 65
 Pioche, Nevada, localities near..... 7k, 31, 31a, 31u, 333a, 333b
 Pioche formation (Lower Cambrian), in detailed section in House Range, Utah, listing included, and correlated species and localities..... 158
 localities in..... 413, 31a, 33i, 52i
 species and localities in Nevada correlated with..... 140
Plaziomys ? deflecta group, classification of, by Ulrich..... 308
Planilimbata limestone, in generalized section for Sweden, Denmark, Finland, and Norway, listing species and localities. See also *Megalaspis planilimbata* zone..... 144
 Platform, defined..... 295
 discussed..... 309-310
 Hall and Clarke on..... 309
 Platform-bearing brachiopods, development of..... 309
Platystrophia, classification of, by Ulrich..... 308
 compared with *Eoarthia remnicha*..... 787
 no Cambrian representatives..... 320
Plectorthis, classification of, by Ulrich..... 308
 discussed..... 772
 muscle scars of, discussed by Ulrich..... 308
 no Cambrian representatives..... 320
 reference to, of *Protorthis hunnebergensis* discussed..... 741
 See also *Orthis (Plectorthis)*.
plicatella, shell section figured..... text fig. 12, 299
whitfieldi, compared with *Billingsella* by Ulrich..... 308
 discussed by Ulrich..... 308
 muscle scars of, discussed by Ulrich..... 308
 Pleurocoeles, defined..... 295
 shown in figure..... 374
 vessels of, shown in figure..... 374
plicatella, see *Billingsella*.
 Põddrus, Esthonia, Russia, locality near..... 337e
 Podolova (Putalova?), St. Petersburg, Russia, locality at..... 366a
pogonipensis, see *Lingulella*.
 Pogonip limestone, detailed section, listing included and correlated species and localities..... 139
 mentioned..... 517, 688, 689, 777
 Pogonip limestone (Lower Ordovician), localities in..... 63,
 201a, 202, 203, 204, 209, 214a, 214b, 221
 Pogonip limestone (Passage beds), localities in..... 201, 203a, 211
 Point Amour, Labrador, locality at..... 392i
 Point Levis, Quebec, localities at..... 319, 319a, 319d, 319i, 392j
 Poland, Cambrian species of, listed..... 120-121
 Pole Creek, Madison County, Montana, locality on..... 149a
politus, see *Diclitomus*.
 Polk County, Tennessee, locality in..... 128a
 Polk County, Wisconsin, localities in..... 78,
 78h, 78c, 78s, 82, 82s, 328b, 328e, 328f, 328h, 328m, 328n
Polyphyma zone (Upper Cambrian), locality in..... 304b
Polytachia, compared with *Clarkella*..... 809
 "*montancnsis*," type of *Clarkella*..... 809
 Pompeckj, J. F., acknowledgments..... 12

 Spain, Cambrian species of, listed..... 120-121
 localities in..... 350, 350a, 350b
 Sparagmite sandstone (Lower Cambrian), in generalized section for Sweden, Denmark, Finland, and Norway, listing species and localities..... 146
 locality in..... 8y
spatula, see *Lingulella* (*Lingulepis*).

- Species, habitat of, discussed 159
 zoological list of, giving page and plate references, and general geographic and stratigraphic distribution 98-109
 zoological list of Asiatic Cambrian, giving geographic distribution, by countries 121-122
 European Cambrian, giving geographic distribution by countries 120-121
 European Ordovician 123
 North American Cambrian, giving geographic distribution by States and geologic provinces 114-119
 North American Ordovician 122-123
 South American and Australian Cambrian 122
- Spence, R. S., species named for 737
spencei, see *Nisusia (Jamesella)*.
- Spence shale (Middle Cambrian), apparent equivalent of, in detailed section in House Range, Utah, listing included and correlated species and localities 158
 in detailed section in Blacksmith Fork, Utah, listing included and correlated species and localities 152
 Spence shale member of the Ute formation (Middle Cambrian), localities in 31d, 32p, 54 l, 55c, 55e, 163
- Spines, presence in Brachiopoda discussed 302
spinosa, see *Acrotreta*.
- Spirifer*, mentioned 785
spissus, see *Obolus (Lingulobolus)*.
- Splanchnocoel, defined 295
 shown in figure 374
- Spondylium, defined 295
 discussed 307-308
 Schuchert on 308
 Ulrich's notes on 308
- Sponge Mountain, Llano County, Texas, locality near 14b
 Spring Creek, near Center, Alabama, locality on 95a
- Springer, Oklahoma, detailed section of Arbuckle limestone near, listing included and correlated species and localities 141-142
 localities near 12k, 12m, 12n
- Spring Hill Canyon, Bridger Range, Montana, locality in 147a
- Spring Mountain Range, Nevada, locality in 7n
spurri, see *Acrothele*.
- squamosa*, see *Lingulella (Lingulcpis)*.
- Sta. Benigna, Bohemia, locality at 303c
- Stansbury Range, Utah, localities in 32f, 32g, 32j, 32k, 32o, 34u, 34v
- Staraja Ladoga, Novgorod, Russia, locality at 336j
- Starr, R. P., species named for 559
starr, see *Lingulella (Lingulcpis)*.
- Steel Ford, Cowan Creek, Alabama, locality near 94
- Stenothecca*, reference to, of "*Discina cerfaicensis*" discussed 723
- Stephen, British Columbia, localities near 35c, 35g, 35h, 57c, 57g, 57k, 57s, 57y, 58z
 See also Mount Stephen.
- Stephen formation (Middle Cambrian), detailed section listing included and correlated species and fossils 127-128
 localities in 14s, 35k, 57c, 57f, 57g, 57j, 57k, 57y, 58l, 58j, 58 l, 58r, 58w, 58z
- Stillwater, Minnesota, localities at and near 339, 339b
- Stissing, New York, locality near 367d
stissingensis, see *Micromitra (Paterina)*.
stissingensis ora, see *Micromitra (Paterina)*.
- Stissing Mountain, New York, locality on 32
- Stockholm (Province), Sweden, localities in 311a, 311p, 311u, 311v, 321, 321a-d, 321o
- Stockingford shales (Upper Cambrian), locality in 304j
- Stockport paper mill, Columbia County, New York, localities near 29, 338b
- Stone, R. E., species named for 466
stoneanus, see *Obolus (Westonia)*.
- Stoner, Pennsylvania, locality near 50
- Sjora Rör, Oeland Island, Sweden, localities near 310e, 310g, 390a
- Straits of Belleisle, Labrador, localities at 392a, 392c, 392l
- Stratigraphic and geographic distribution tabulated 98-109
- Stratigraphic sections with correlated faunal lists 123-159
- Streitberg, Esthonia, Russia, locality at 396r
striata, see *Billingsella*.
- Stricklandinia*, compared with *Syntrophia* 798
 ? *arochne*, generic reference discussed 798
 ? *orethusa*, generic reference discussed 798
- Strophomena*, compared with *Eostrophomena* 796
 reference to, of *Eoarthis otava*, discussed 774
Eoarthis johannensis, discussed 781
Protarthis humbergensis, discussed 741
- Strophomena*—Continued,
aurora, compared with *Eostrophomena elegantula* 796
rhomboidalis, compared with *Eoarthis johannensis* 781
 "Strophomeno or Strophodonta," compared with *Eoarthis johannensis* 781
 "Strophomena (*Eostrophomena*) *elegantula*," type of *Eostrophomena* 796
- Strophomenacea, classification of 321, 326
 distribution in Cambrian strata 316
 genera and species referred to, described 795-796
- Strophomenidae, cardinal process, discussed 306
 classification of 321, 326
 cruralium, mentioned 309
 distribution in Cambrian strata 316
 genera and species referred to, described 795-796
 general stratigraphic distribution and number of Cambrian genera and species of 112
 no interiors seen 312
 number of Cambrian genera and species of 112
 number of genera and species in monograph 113
- Structure of the shell 296-300
- stuarti*, see *Micromitra (Paterina)*.
subconica, see *Acrotreta*.
subquadrata, see *Nisusia (Jamesella) pcrpasta*.
subsida, see *Acrothele*.
subsida hera, see *Acrothele*.
subsida laevis, see *Acrothele*.
- Sularp, near Lund, Sweden, localities at 321s, 321t
sulcata, see *Acrotreta idahoensis* and *Eoarthis remnicha*.
sulcatus, see *Discinopsis*.
- Sullivan County, Tennessee, localities in 2z, 2z', 374c, 374e
- Summary tables 110-113
- Sun River (North Fork), Powell County, Montana, localities near 3j, 5j
superba, see *Micromitra (Paterina)*.
- Surface ornamentation, discussed 300-303
 importance of, in classification 301
- Sussex County, New Jersey, locality in 11c
- Swallow ranch, White Pine County, Nevada, locality near 8n
- Swansea (Viola), Alabama, locality near 144c
- Swanston, W., bibliographic references 24
- Swanton, Vermont, localities near 25a, 28, 319e, 319f, 319z
swantonensis, see *Micromitra (Paterina) labradorica*.
- Swanton*, described 796
 cardinal area discussed 305
 classification of 321, 326
 compared with *Camorella* 797
 evolution discussed 320
 evolution of 317
 general geographic and stratigraphic distribution of the species referred to 109
 general stratigraphic distribution and number of Cambrian species and varieties of 111
 number of species of, in different types of sediment 160
 stratigraphic position mentioned 318
 surface ornamentation discussed 303
 type species "*Camorella antiqua*" 797
antiqua, described 797
 compared with *Huencella vermontana* 809
 general geographic and stratigraphic distribution tabulated 109
 type specimen not figured.
- wccski*, described 797
 compared with *Swanton* *antiqua* 797
 general geographic and stratigraphic distribution tabulated 109
 type specimen figured Pl. CIV, fig. 6
- Swarow, Bohemia, locality at 303d
- Swasey formation (Middle Cambrian), in detailed section in House Range, Utah, listing included and correlated species and localities 157
 localities in 11w, 30d
- Swasey Spring, House Range, Utah, localities near 15b, 15c
- Swasey Spring road, House Range, Utah, locality on 11o
- Sweden, Cambrian species of, listed 120-121
 generalized section of Cambrian and Ordovician in, listing included and correlated species and localities 144-146
 localities in 8w, 8y, 8z, 9e, 309, 309a-f, 309h-j, 309 l, 309m, 310, 310a-z, 311, 311a-c, 311g-p, 311u, 311v, 320, 320a-z, 321, 321a-v, 321x-z, 323j, 323k, 390, 390a-p
 species of *Obolus* from, listed 379
 stratigraphic position of boulders in Baltic region discussed 454
 See also separate provinces.

Wynnia, described 771
 cardinal area discussed 305
 classification of 321, 325
 evolution of 317
 general geographic and stratigraphic distribution of the species referred to 108
 general stratigraphic distribution and number of Cambrian species and varieties of 111
 number of species of, in different types of sediment ... 160
 stratigraphic position mentioned 320
worthi, described 771
 general geographic and stratigraphic distribution tabulated 108
 type specimen figured Pl. LXXXIX, fig. 4a
 Wyoming, Cambrian species of, listed 114-119
 localities in (Middle Cambrian) 4e, 4j, 4m-o, 170, 171, 171a, 302h, 302l, 302m, 302o, 302x, 302y, 340c, 340d
 localities in (Upper Cambrian) 14k, 168, 302c-e, 302g-h, 302p, 302n
 note on stratigraphic position of localities in 144
 stratigraphic position of localities in, discussed 137
 Wysogórski, Johann, bibliographic reference 26
 Yanceys Bend, Coosa River, Alabama, locality at 92x
 Yellowstone National Park, Wyoming, localities in 4i, 302b, 302c, 302f-h, 302I
 Yellowstone River, Montana, locality east of 4r
 Yenchang, China, localities at and near C1-7, C9, C10, C12, C61, C62, C63, C64
 Yogo limestone (Upper Cambrian), localities in 302q, 302r
 note on stratigraphic position of 137
 York, Pennsylvania, localities at and near 8q, 48d, 49a, 49e, 50, 50a, 346c
 York County, Pennsylvania, localities in 8q, 48d, 49, 49a-c, 49e, 49w, 50, 50a, 346, 346c
Yorkensis, see *Acrothelc*.
 Yorke Peninsula, South Australia, localities on 315, 315a
Yorkia, described 611
 cardinal area discussed 305
 classification of 321, 324
 compared with *Quebecia* 611
 evolution discussed 319
 evolution of 317
 general geographic and stratigraphic distribution of the species referred to 104
 general stratigraphic distribution and number of Cambrian species and varieties of 111
 muscle scars not shown in 313
 number of species of, in different types of sediment ... 160
 reference to, of *Yorkia ? miqueli* discussed 612
 reference to, of *Yorkia ? orientalis* discussed 612
 reference to, of *Yorkia ? washingtonensis* discussed ... 612, 613
 shell substance 297
 stratigraphic position mentioned 318
 type species *Yorkia wanneri* 611
 vascular markings discussed 311
? miqueli, described 611
 general geographic and stratigraphic distribution tabulated 104
 type specimen figured Pl. LXXXII, fig. 4
? orientalis, described 612
 general geographic and stratigraphic distribution tabulated 104
 type specimen figured Pl. LXXXII, fig. 3
wanneri, described 612
 compared with *Yorkia ? orientalis* 612
 general geographic and stratigraphic distribution tabulated 104
 type of *Yorkia* 611
 type specimen figured Pl. LXXXII, fig. 1g
? washingtonensis, described 613
 general geographic and stratigraphic distribution tabulated 104
 generic reference discussed 612
 type specimen figured Pl. LXXXII, fig. 2
 Youngs Creek, Ovando quadrangle, Montana, localities near 4q, 4q', 4w, 8j
 Youngs (McPhees) Point, Nova Scotia, locality on 307d
 Ytternaeset, Åland Island, Finland, localities at 311q, 311y
 Zarskoe Selo, St. Petersburg, Russia, localities at 336g, 396z
 Zbirov, see Sbirov.
zeno, see *Eoorthis*.
zenobia, see *Micromitra*.
zetus, see *Obolus*.
zeus, see *Lingulella*.
 Ziegelskoppel, Esthonia, Russia, locality at 396t
 Zittel, K. A. von, bibliographic reference 26
 Zone BIIIa or BIII β (Ordovician), locality in 337j
 Zone C of Westergård (Passage beds), locality in 310w
 Zone 1 of Moberg and Segerberg (Upper Cambrian), locality in ... 309b
 Zone 2 of Moberg and Segerberg (Upper Cambrian), locality in ... 309a
 Zone 3 of Moberg and Segerberg (Upper Cambrian), localities in 390b, 390c
 See also *Shumardia* zone and *Ceratopyge* slate.
 Zone 4 of Moberg and Segerberg (Passage beds), localities in ... 309, 310
 See also *Ceratopyge* limestone.
 Zoological discussion 291-326
zoppi, see *Obolus*.
